can clearly be used in finding the new set of cells and/or edges that needs to be visited in the grid, building the solution of the next silhouette query based on the solution of the previous query.

bounded by $O(n)$ and hence is in the same order of the magnitude of the input, large models can take full advantage of the real memory of contemporary workstations. Because large models is where the presented algorithm shines, even a decrease by a constant factor of the memory use is significant, and effort should be invested to minimize this memory overhead.

The use of this efficient silhouette extraction algorithm should be examined in various other applications from hidden line removal, through general swept volume of object $O$, to collision detection [7].

While in this work, we have selected a circumscribing cube for simplicity, one should expect somewhat better behavior if a tetrahedra will be used, minimizing the number of faces that need to be processed. While each face is now somewhat more complex, the overall cost should be evaluated, seeking the best convex circumscribing polyhedra. Furthermore, because objects have different silhouette complexity from different views, it is also worth while to ask the question of the best circumscribing convex polyhedra, for some special objects.

Because of the way the arcs are centrally projected onto the plane of the circumscribing polyhedra, one could also have chosen to subdivide the planes in a radial way. This subdivision scheme should improve our results since the associated segments are expected to be more densely populated in the centers of the six planes, due to the behaviour of the central projection, while making the traversal of cells for a given $C_i(\vec{V})$ more complex. This density should be computed to follow the Riemannian metric of the central projection. In addition, the influence of the resolution of the grid on the query time, considering both the shape of the model and the number of silhouette edges, is yet to be explored as well, for optimality.

Finally, we have not exploited the fact that the stabbing line is continuously moving. This coherency

4 Conclusion

We have presented an optimal algorithm to interactively extract the silhouette edges of polygonal model(s), that is linear in the output silhouette set.

Several improvements can augment the presented method. First, this algorithm is limited by the real memory capacity of the exploited system. While the memory consumption of the presented algorithm is

3 Results

We have applied the proposed algorithm to various polygonal objects and recorded the results obtained in Table 1. All results shown were pre-processed in a very short time from a fraction of a second to few seconds. All computations were conducted on an O2 SGI system equipped with a 180 Mhz R5000.

The presented real time silhouette query results have been calculated from an average of one thousand different views. Note that even though we are not using an optimal algorithm for resolving the stabbing query, we have obtained a significant reduction in the computation time of the silhouette query by factors that range from ten times and up to almost one hundred times less than the straightforward or naive
Figure 6: Two segments, \( \overline{A(E_i)} \), \( i = 1, 2 \), and a query line, \( \mathcal{L}_i(\overline{V}) \), processed in three grids of different resolutions. Note that in (c), \( \overline{A(E_2)} \) need not be tested against \( \mathcal{L}_i(\overline{V}) \), because \( \overline{A(E_2)} \) and \( \mathcal{L}_i(\overline{V}) \) share no common cells.

Intersection test, avoiding unnecessary further redundant computations. Obviously, the finer the grid, the less line segments one needs to test in each query, but more cells are to be visited and more memory is to be allocated.

Algorithm 2 summarizes the first two pre-processing stages that were described in Sections 2.1 and 2.2. The time complexity of this pre-processing stage is clearly bounded by \( O(n g^2) \) where \( g \) is the number of cells in each one of the six grids, \( G_i \). Hence, for a grid with a fixed size, the time complexity of Algorithm 2 is \( O(n) \).

Algorithm 3 summarizes the processing of the real time stubbing query, using the simple grid based approach. Assume that the average edge covers \( m \) cells on grid \( G_i \) and select a grid resolution of size \( \sqrt{n} \) by \( \sqrt{n} \) for \( G_i \). Hence, the average density of a cell will be \( m \) edges per cell. A line cutting through \( G_i \) will visit \( O(\sqrt{n}) \) cells or \( O(m \sqrt{n}) \) edges will be examined for being silhouette edge, on the average. Unfortunately, the value of \( m \) is highly geometry dependent, a hindering factor which prevents us from establishing a clear upper bound for the grid based query algorithm. Moreover, it is clear that one can stage cases for each we will unnecessarily test \( O(n) \) edges, using Algorithm 3, even when \( s = O(\sqrt{n}) \). Nevertheless, the average behavior of this algorithm is far better that the naive approach presented in Algorithm 1 as will be demonstrated in Section 3.
Figure 5: Three projection planes of the Gaussian Sphere data, $\mathcal{G}_S$, onto a circumscribing cube. Data is from the glass object of Figure 1. Note that all drawn polylines are, in fact, formed out of numerous small connected line segments. Planes $X = -1, Y = \pm 1$ are similar to Plane $X = 1$. Also note the missing edges on the boundaries which are added at random, to either one of the two faces that share that edge.

A complex algorithm that based on a new hierarchical space-partitioning scheme defined by Chazell et al. [3]. Both methods move the initial problem into half-plane range-searching problem, which consists of reporting on points in one part of an hyper-plane.

It is clear that if $\Delta$ is in the order of the number of line segments, $n$, the segments of interest can be reported in $O(\sqrt{n})$. Because $s$ is also in the order of $O(\sqrt{n})$, we are able to report the silhouette edges in output sensitive manner that is linear in the output set and hence optimal.

As part of the implementation of this work, we have chosen a simple yet efficient alternative to the above optimal stabbing query algorithms. As the segments are located in six bounded planar square areas, we impose on these six planar square faces, six grids that are denoted $\mathcal{G}_i$, $i = 1, \ldots, 6$, and are of some prescribed resolution. Each cell, $C \in \mathcal{G}_i$, stores the line segments from the set of projected arcs, $\mathcal{A}(E_i)$, that intersects that cell. Then, and following Lemma 2, the query consists of visiting only the set of cells that are stabbed by line $L_i(\bar{V})$ and reporting segments $\mathcal{A}(E_i)$ that indeed intersect with $L_i(\bar{V})$.

Figure 6 illustrates several grids of different resolutions containing two line segments and the infinite query line, $L_i(\bar{V})$. In Figures 6 (a) and (b), $\mathcal{A}(E_1)$ and $\mathcal{A}(E_2)$ have at least one common cell with $L_i(\bar{V})$. Hence, the query process will visit the two segments. Nonetheless, in Figure 6 (c), no cells are simultaneously crossed by $\mathcal{A}(E_2)$ and $L_i(\bar{V})$, so $\mathcal{A}(E_2)$ is not considered.

A line segment, $\mathcal{A}(E_i)$, might be contained in more than one cell. Therefore, and in order to prevent from testing $\mathcal{A}(E_i)$ several times for intersections against $L_i(\bar{V})$, we mark $\mathcal{A}(E_i)$ as tested on its first
\( \{\mathcal{P}_i \cap \mathcal{F}_i\}_{i=1}^6 \). In general, a cube and an infinite plane might intersect in a polygon with three to six edges. Nevertheless, because the plane \( \mathcal{P}_i \) contains the origin, \( O \), which is the center of the cube, the resulting intersection of the cube and \( \mathcal{P}_i \) might consist of either four or six line segments, \( \mathcal{L}_i(\hat{V}) \), forming a closed convex polygon. Then, the central projection allows us to perform a second mapping that further simplifies the complexity of answering silhouette Query 1:

**Lemma 2**

\[
E_i \in \mathcal{S}(O, \hat{V}) \iff \overline{A(E_i)} \cap \mathcal{L} \neq \emptyset.
\]

**Proof:** From Lemma 1, we have \( E_i \in \mathcal{S}(O, \hat{V}) \iff \overline{A(E_i)} \cap \mathcal{P}_i \neq \emptyset \). Hence, we need to show that \( \overline{A(E_i)} \cap \mathcal{L} \neq \emptyset \iff \overline{A(E_i)} \cap \mathcal{P}_i \). Now \( \overline{A(E_i)} \cap \mathcal{P}_i = \overline{A(E_i)} \cap (\mathcal{P}_i \cap S^2) \). Furthermore, \( \mathcal{L} \) is the central projection of \( \mathcal{P}_i \cap S^2 \) and \( \overline{A(E_i)} \) is the central projection of \( A(E_i) \). Then, relation (3) is a direct consequence of the bijective property of the central projection of the unit sphere onto its circumscribing cube, preserving all intersections.

Figure 5 shows an example of the \( \mathcal{F}_i \) planes that are obtained, after the projection of the \( \mathcal{G}_S \) data of the wine glass of Figure 1 onto six faces of a circumscribing cube. The symmetry of the surface of revolution of the glass, yields the same projection for the four planes of \( X = \pm 1 \) and \( Y = \pm 1 \) and hence three of these four planes are omitted from the figure.

So far, completing the pre-processing stages, we have obtained a set of six planes that contain \( O(n) \) line segments representing all the edges of the object(s). In the next section, Section 2.3, Lemma 2 will be employed to efficiently compute the silhouette edges of the polygonal model, from an arbitrary viewing direction, \( \hat{V} \).

### 2.3 Querying the silhouette edges

The problem in hand can be formulated as follows. Given a set of \( O(n) \) line segments, \( \{\overline{A(E_i)}\}_{i=1}^n \), in the plane, one is seeking the line segments that are intersected by a prescribed infinite line \( \mathcal{L}_i(\hat{V}) \). This problem has a rich literature which we do not attempt to survey here; we only recall the results that were obtained for this *stabbing or ray tracing query* as it is sometimes called. Chazelle [2] derived lower bounds for this problem of \( \Omega(n/\sqrt{\Delta}) \) where \( \Delta \) is the storage used. Matoušek [8] gave an algorithm whose performance matches this lower bound. Yet, the implementation of his algorithm is based on a linear-space data structure which is complicated. In Argawal and Sharir [1], similar results are presented with
Figure 4: Projection onto a circumscribing cube of the two associated arcs, $A(E_1)$ and $A(E_2)$, from Figure 3.

circumscribes the sphere guarantees that the central mapping from the unit sphere to the polyhedra is indeed bijective.

We have selected the convex circumscribing polyhedra to be an axis-parallel cube due to the simplicity in the expected projections onto the six faces of the cube. Each arc $A(E_i)$ on the Gaussian Sphere is centrally projected along with its two end points’ normals onto the circumscribing cube. Recall that $A(E_i)$ always span less than 180 degrees. Then, the central projection might project $A(E_i)$ on the cube as one to four line segments on one to four adjacent faces of the cube, respectively. See Figure 4.

Let $N_1(E_i)$ and $N_2(E_i)$ denote the central projections of $N_1(E_i)$ and $N_2(E_i)$ onto the cube. Again, if $N_1(E_i)$ and $N_1(E_i)$ belong to the same face of the cube, the projection of the arc is the simple line segment $N_1(E_i)N_2(E_i)$. Otherwise, we obtain a list of up to four line segments on adjacent faces of the cube. The projection of $A(E_i)$ onto the cube is denoted the associated segment of $E_i$, $A(E_i)$.

Denote by $F_i$, $i = 1, .., 6$, the six faces of the circumscribing cube, and let $\mathcal{L} = \{L_i(\overline{v})\}_{i=1}^6 = \ldots$
Lemma 1

\[ E_i \in S(O, \overline{V}) \iff A(E_i) \cap P_\overline{V} \neq \emptyset. \]  

**Proof:** From Equation (1), \( E_i \) is a silhouette edge if and only if \( \left\langle N_1(E_i), \overline{V} \right\rangle \left\langle N_2(E_i), \overline{V} \right\rangle \leq 0. \)

Consider first the case for each \( \left\langle N_j(E_i), \overline{V} \right\rangle = 0 \), for \( j = 1 \) or \( j = 2 \). Then, Equation (1) holds and hence \( E_i \) is a silhouette. But if \( \left\langle N_j(E_i), \overline{V} \right\rangle = 0 \), \( N_j(E_i) \) must be orthogonal to \( \overline{V} \), or \( N_j(E_i) \subseteq P_\overline{V} \). Therefore, \( A(E_i) \cap P_\overline{V} \neq \emptyset \).

Now assume \( \left\langle N_1(E_i), \overline{V} \right\rangle \left\langle N_2(E_i), \overline{V} \right\rangle < 0 \). From the continuity of \( A(E_i) \), it is clear that there exist \( N \in A(E_i) \) such that \( \left\langle N, \overline{V} \right\rangle = 0. \) Then again, \( N \) must be in \( P_\overline{V} \). Therefore, \( A(E_i) \cap P_\overline{V} \neq \emptyset \).

Finally assume \( \left\langle N_1(E_i), \overline{V} \right\rangle \left\langle N_2(E_i), \overline{V} \right\rangle > 0. \) Then, both \( N_1(E_i) \) and \( N_2(E_i) \) are on the same side of \( P_\overline{V} \). Clearly the shortest great geodesic arc on \( S^2 \) between \( N_1(E_i) \) and \( N_2(E_i) \) does not intersect \( P_\overline{V} \). This geodesic is exactly \( A(E_i) \). Therefore, \( \left\langle N, \overline{V} \right\rangle \neq 0, \forall N \in A(E_i) \). Hence, no vector in \( A(E_i) \) is contained in \( P_\overline{V} \), or \( A(E_i) \cap P_\overline{V} = \emptyset \).

The other direction follows the exact same (yet reversed) line of reasoning, concluding the proof.

The silhouette extraction problem has therefore been reduced into searching the (associated) arcs, \( A(E_i) \), on the unit sphere of \( G_S \), that are crossed by the viewing plane, \( P_\overline{V} \). An edge with two identical associated normals will never be displayed. Hence, and while mapping all the normals to the \( G_S \), we filter out, during this pre-processing stage, edges with zero arc-length associated arcs.

### 2.2 Projecting the Gaussian Sphere onto a Circumscribing Cube

As in many cases, it is easier to deal with a two dimensional geometry rather than a three dimensional one. The goal of this stage is to map the three dimensional query problem of arcs on the unit sphere into a two dimensional query problem of line segments on a two dimensional plane. Toward this end, we employ the central (or gnomonic) projection [6]. Every point \( P \in A(E_i) \) is projected by the central projection along a ray that emanated from the origin of the Euclidean space, \( O \), which is also the center of \( G_S \). Given some planar face \( F_i \), the central projection of \( P \) on \( F_i \) is the intersection point of ray \( \overline{OP} \) and \( F_i \), \( \overline{OP} \cap F_i \).

Interestingly enough, great arcs such as \( A(E_i) \), are centrally projected into line segments in \( F_i \).

Here, the normal information on the Gaussian Sphere, \( G_S \), is centrally projected onto a convex circumscribing polyhedra along with all its associated arcs. The convexity condition ensures that each point on the unit sphere is centrally projected to exactly one point on the polyhedra. The fact that the polyhedra
planes of a circumscribing cube. This second stage is described in Section 2.2. The third stage is the stage that satisfies the silhouette query, and is described in Section 2.3. This query request is the only stage that is conducted during the interactive session, in real time.

2.1 The Mapping onto the Gaussian Sphere

Given a viewing direction, the containment of edge $E_i$ in $S(O, \vec{V})$ solely depends on its two associative unit normals, $N_1(E_i)$ and $N_2(E_i)$. Denote by $O$, the origin of the Euclidean space, and let arc $A(E_i) = \angle N_1(E_i)ON_2(E_i)$ be denoting the associated arc of $E_i$ on the Gaussian Sphere (see Figure 3). arc is a great arc and while there exist two great arcs between $N_1(E_i)$ and $N_2(E_i)$, the shortest one is the only one considered. Hence, and being a dihedral angle of two adjacent polygons, $A(E_i)$ is a great arc that always spans less than 180 degrees.

Let $P_{\vec{V}}$ be the plane that is orthogonal to $\vec{V}$ through the origin $O$. $P_{\vec{V}}$ is denoted the viewing plane. Then,
view-independent and will always contribute to the display of the object. In other words, \( B \) solely depends on the geometry of the object, \( B = B(\mathcal{O}) \). Figure 1 (b) shows, in a gray line, the boundary set of the polygonal model of the wine glass shown in Figure 1 (a).

Efficient extraction of silhouettes, given the viewing direction, is potentially useful for many other applications, such as hidden line removal, collision detection, diameters of objects, and the construction of the swept volume of \( \mathcal{O} \) along some rotational trajectory. Nevertheless and while the presented approach is clearly useful for all these applications, we will demonstrate the use of the proposed algorithm only in the application of real time display.

This paper is organized as follow. In Section 2, we present the different stages of the algorithm. In Section 3, some result are presented, while we conclude in Section 4. All the examples presented in this paper were created with the aid of the IRIT [5] solid modeling system that is developed at the computer science department, Technion, Israel.

2 Algorithm

In this section, we introduce the output sensitive extraction method of silhouette edges. We assume that the input, two-manifold, polygonal object \( \mathcal{O} \) has already been regularized. We begin the pre-processing stage, in Section 2.1, by mapping the normals of all the polygons of \( \mathcal{O} \), along with all the edges of the neighboring polygons of \( \mathcal{O} \), onto a data structure called the Gaussian Sphere [4], \( G_S \), on \( S^2 \), the unit sphere. Then, in the second pre-processing stage, the data on the Gaussian Sphere is projected onto six different
Algorithm 1

Input:
\[ O, \text{ A model to interactively display its silhouette; } \]
\[ \bar{V}, \text{ A viewing direction for the real time query; } \]

Output:
\[ S(O, \bar{V}), \text{ the silhouettes of } O \text{ from viewing direction } \bar{V}; \]

Algorithm:
NaiveSilhExtct( O, \bar{V} )
begin
\[ S(O, \bar{V}) \leftarrow \{ \}; \]
\[ E \leftarrow \text{ All } n \text{ edges of all polygons, } P_j \in O, \ j = 1, \ldots, O(n); \]
For each edge \( E_i \) in \( E \) do
\[ \text{If } \left( \langle N_1(E_i), \bar{V} \rangle \langle N_2(E_i), \bar{V} \rangle \leq 0 \right) \text{ then } \]
\[ S(O, \bar{V}) \leftarrow S(O, \bar{V}) \cup \{ E_i \}; \]
endfor;
return \( S(O, \bar{V}) \);
end.

other. \( E_i \) is called a non-regular edge. To complicate things, note the different unit normals of polygons \( P_2 \) and \( P_4 \), \( N_2 \) and \( N_4 \). From the given viewing direction, and according to Equation (1), only a portion of \( E_i \) is a silhouette edge, the portion that is shared by \( P_1 \) and \( P_4 \).

The solution lays in the regularity condition we are about to impose over the polygons of \( O \):

**Definition 2** A two-manifold object, \( O \), is called regular if no vertex in \( O \) lays on the interior of an edge of a neighboring polygon.

In other word, for a two-manifold regular object, all edges are shared by at most two polygon.

In the example of Figure 2 (a), the remedy is found by splitting polygon \( P_1 \) into two new polygons, \( P_1^a \) and \( P_1^b \), in such a way that we obtain two different edges that exactly match the two respective edges of polygons \( P_2 \) and \( P_4 \). This entire process is called regularization.

1.3 The Detection of Boundary Edges

Geometric objects may be open. For example in Figure 1 (a), the top and the bottom of the surface of revolution of the wine glass is open.

All edges that have only one associated polygon are called open edges. The set of all open edges is denoted the object’s boundary or \( \mathcal{B} \), and is also called the set of boundary edges. Unlike \( S(O, \bar{V}) \), \( \mathcal{B} \) is
Figure 1: In (a), a polygonal model of a wine glass is shown. In (b), the boundary edges are shown in gray while the silhouette are shown in black.

Nevertheless, this singularity can clearly be tested via the examination of the individual signs of $\langle N_j(E_i), \vec{V} \rangle$, $j = 1, 2$ and will be ignored from now on.

A naive algorithm to extract $S(\mathcal{O}, \vec{V})$ can traverse all $O(n)$ polygons, $\mathcal{P}_j \in \mathcal{O}$, $j = 1, \ldots, O(n)$ and extract the set $\mathcal{E}$. Then, for each edge $E_i \in \mathcal{E}$, $i = 1, \ldots, n$, the two associated polygons of $E_i$ are identified, and, following Equation (1), a test whether $E_i$ is a silhouette edge or not can be conducted. See algorithm 1.

The time complexity of Algorithm 1 is clearly of order $O(n)$, again assuming the number of edges of every polygon is bounded by some constant. But even such an algorithm requires some pre-processing. First, the set $\mathcal{E}$ must be computed. Then, given $E_i \in \mathcal{E}$, the identification of $\mathcal{P}_1$ and $\mathcal{P}_2$ requires topological neighborhood information. Furthermore, while Algorithm 1 assumes a two-manifold object, each edge might be shared by more than two polygons, a singular condition that can be resolve by neither Algorithm 1 nor the output sensitive algorithm we are about to present as part of this work. In Section 1.2, we will introduce the problem as well as a possible simple remedy.

1.2 Regularized object

An edge can be shared by more than two polygons, in a two-manifold object. For example, consider Figure 2 (a). A single edge, $E_i$, is shared by polygon $\mathcal{P}_1$ on one side, and by polygons $\mathcal{P}_2$ and $\mathcal{P}_4$ on the
The set of all silhouette edges of $O$ as viewed from direction $\vec{V}$ will be denoted $S(O, \vec{V})$. While we are allowed to pre-process all the geometric data off-line, we would like to answer the following query in the most efficient way:

**Query 1** Given a viewing direction, $\vec{V}$, find the set of edges of polygon object $O$, that are silhouette edges from $\vec{V}$, $S(O, \vec{V})$.

Let $\mathcal{E}$ be the set of all edges of all the polygons of $O$. While each edge typically shows up twice, in each of its two associated polygons, we count this edge only once throughout this work. Let the number of polygons in $O$ be of $O(n)$ and denote by $s$ the number of silhouette edges, $|S(O, \vec{V})|$. Assume the number of edges of a single polygon is bounded. Then, the size of $\mathcal{E}$, $|\mathcal{E}|$, is also $O(n)$. Hereafter, we assume $|\mathcal{E}| = n$.

Consider a polygonal approximation of a sphere of radius $r$ that is tiled by small triangles of area $d$ each. The area of the sphere is proportional to $r^2$ while the silhouette edges of the sphere are proportional to the length of a great circle on the sphere or proportional to $r$. Therefore, $n = O\left(\frac{r^2}{d}\right)$ whereas $s = O\left(\frac{r}{d}\right)$. In other words, the number of polygons in a spherical object relates to the area of the object is a similar way to the relation between $s$ and the diameter of the sphere.

One can clearly construct objects where the number of silhouette edges, $s$, will be proportional to the total number of edges, $n$. For example, consider a polygonal approximation of a cylinder, where $s \geq \frac{n}{3}$ holds for any view. In contrast, one can envision an object that from a certain view, $s$ is arbitrarily small, when an arbitrarily freeform complex feature of the model generates no silhouette edge.

Nevertheless and on the average, we will expect that the number of silhouette edges will be proportional to $\sqrt{n}$. In this work, we are aiming at an *output sensitive extraction of silhouettes* and hence, we seek an algorithm to answer silhouette Query 1 with a time complexity of $O(\sqrt{n} + s)$.

### 1.1 The Detection of Silhouette Edges

Given edges $E_i \in \mathcal{E}$, $i = 1, \ldots, n$ and a viewing direction, $\vec{V}$, we are interested in deciding if $E_i \in S(O, \vec{V})$. Consider again the two associated polygons of $E_i$, $\mathcal{P}_1(E_i)$ and $\mathcal{P}_2(E_i)$. Let the two normals of $\mathcal{P}_1(E_i)$ and $\mathcal{P}_2(E_i)$ be $N_1(E_i)$ and $N_2(E_i)$, that are also denoted as the *associated normals* of $E_i$. Then and following Definition 1, one can express the constraint for $E_i$ to be a silhouette edge as,

$$E_i \in S(O, \vec{V}) \iff \langle N_1(E_i), \vec{V} \rangle \langle N_2(E_i), \vec{V} \rangle \leq 0.$$  \hspace{1cm} (1)

Unlike Definition 1, Equation (1) includes the special case were one of the two associated polygon is invisible (back facing) while the other presents a zero area (with a normal that is orthogonal to
Output Sensitive Extraction of Silhouettes
from Polygonal Geometry

Abstract
An algorithm to allow real time interactive display of silhouettes of complex polygonal object(s) is presented. An off-line pre-processing of all the edges of all polygons allows the efficient extraction of the silhouette edges, in real time. During the interactive session, the time complexity of extracting the silhouette edges is linear in the number of output edges in the extracted silhouette, and is typically in the order of $O\left(\sqrt{n}\right)$, where $n$ is the number of polygons in the scene. The time complexity of the pre-processing stage is linear in $n$.

Key Words: Silhouette, Real Time Display, Gaussian Sphere, Range Searching.

1 Introduction

Consider a polygonal object, $O$, and some viewing direction, $\vec{V}$. Throughout this work, we assume that $O$ is a two-manifold. That is, every point on every edge, $E_i \in O$, serves as a boundary point of exactly two polygons, $P_1(E_i)$ and $P_2(E_i)$, denoted the associated polygons of $E_i$. A polygon is considered locally visible if it presents a non zero area toward the viewing direction, $\vec{V}$. Then,

**Definition 1** $E_i$ is a silhouette edge if exactly one of its two associated polygons is locally visible from $\vec{V}$.

Local visibility does not ensure that a polygon is indeed visible. Nevertheless, local invisibility guarantees the invisibility of the polygon.

The silhouette edges of a given geometry are highly intuitive and useful in depicting the shape of the object, reflecting on the limits or the horizons of the geometry. The silhouette edges provide significant cues to the objects’ shape and serves well in tools that display and/or portray geometry.
