Parallel Copying Garbage Collection  
using Delayed Allocation  

Erez Petrank\textsuperscript{*}  Elliot K. Kolodner\textsuperscript{†}  

Abstract  
We present a new approach to parallel copying garbage collection on symmetric multiprocessor (SMP) machines appropriate for Java and other object-oriented languages. Parallel, in this setting, means that the collector runs in several parallel threads.  
Our collector is based on a new idea called delayed allocation, which completely eliminates the fragmentation problem of previous parallel copying collectors while still keeping low synchronization, high efficiency, and simplicity of collection. In addition to this main idea, we also discuss several other ideas such as termination detection, balancing the distribution of work, and dealing with contention during work distribution.  

Keywords: Language design and implementation, Parallel garbage collection, Memory management.  

1 Introduction  
Java is an important new technology, especially as the language of internet programming. This popularity is attributed to Java being a simple, object oriented, secure, portable, and platform independent language. High performance is a crucial property of any Java Virtual Machine (JVM), and since

Java provides automatic memory management and garbage collection, one of the first candidates for performance improvements is to incorporate an efficient allocator and garbage collector into the runtime.

Initially, Java was introduced as a technology for client machines on the desktop. Recently, it has also gained popularity for server machines, mainly because of its platform independence. Today’s characteristic server platforms employ symmetric multiprocessors in order to increase their computing power. The use of multiprocessors is also increasing for desktop machines. Thus, taking full advantage of the multiprocessor is essential for good Java performance on these platforms.

Many garbage collection algorithms, including advanced algorithms first designed for uniprocessors, do not take advantage of multiprocessors. In these algorithms, all application threads are stopped while a single thread executes the collector on a single processor and all other processors are idle. Thus, these collectors are not appropriate for use on a multiprocessor. A parallel garbage collector keeps all processors busy doing useful work even during collection.

In this paper we present a design for a parallel collector. Our parallel collector is appropriate both for Java and for other object oriented programming languages on a multiprocessor.

Another way to use multiprocessors efficiently is to employ a concurrent garbage collector. In such a collector, a single garbage collection thread runs concurrently with the program threads (see for example [2, 21, 22, 7, 6, 9, 8, 17]). Potentially, all processors can be kept busy during collection. However, as the number of processors and program threads increase, a single garbage collector thread may not keep up with the allocation demands of the many program threads (see for example [1, 9]), and the system may end up being single threaded as it waits for the garbage collector to free space. The scalability of the system depends on the collector being able to collect as fast as the application allocates. Thus, a concurrent collector can also benefit from the parallelization of the collector thread.

1.1 Contribution of this work

Before going on, let us define terminology for the rest of this paper. We denote by parallel collection a collection which is run while the application program is stopped and several parallel collector threads perform the collection. We denote by concurrent collection a collection performed by one or more collector threads that run concurrently together with the application
threads.

The main contribution of this work is the design of a parallel garbage collector appropriate for Java and other object oriented languages on SMP server machines. We present a parallel version (for SMP machines) of the well known copying garbage collector introduced in [20, 11, 3]. The advantages of the copying garbage collection are the fact that the heap is compacted in each collection, the low complexity of the algorithm which touches only the live objects (rather than touching all heap as a mark & sweep algorithm does), and the simplicity of allocation (controlled increase of a pointer).

Our main new idea is delayed allocation during the parallel collection (presented in Section 4.2). Using delayed allocation, a collector thread does not copy an object immediately; rather, it waits until it has a group of objects, and then allocates memory for all objects in the group at once and copies those objects. Delayed allocation completely eliminates the fragmentation problem of previous parallel collectors [13, 5, 19, 14, 15]. This method incurs low synchronization (as low as in previous work), it is simple (even simpler than some of the previous solutions), and it is as efficient as previous solutions.

We believe that our basic ideas can also be generalized to parallelize other copying-based garbage collection algorithms.

The prime motivation in designing this algorithm is demonstrating the possibility of avoiding fragmentation completely (in a parallel copying garbage collection) at a negligible efficiency cost. State-of-the-art collectors do not achieve this goal but usually get quite close for typical benchmarks, achieving a low percentage of fragmentation. From a practical point of view, note that without fragmentation, copying collection always succeeds. With fragmentation, a collection of a tight heap may run out of space to complete. In that case there must exist complicated code to bail out somehow while preserving correctness. This code is expected to almost never execute – the worst kind of code to have in a system.

In addition to this main contribution, we offer several new ideas for designing a parallel copying garbage collector. First, we consider termination detection. An efficient termination detection is tricky and a previous attempt to describe a termination detection protocol [10] was faulty. We point out this problem and recommend the alternative proposed in [12]. We also discuss work distribution: first, how to break the work into small pieces to be jointly performed by the parallel collector threads, and second, what machinery should be used to incur low contention on distributing the pieces
of work among the collector threads.

In addition to the aforementioned ideas, we also make several observations important for implementers of a parallel copying collectors. These include items such as dealing with modern SMP memory coherence models, and our list of design goals (in Section 2 below) that should be addressed when designing such a collector.

1.2 Organization

We start in Section 2 with the design goals. In Section 3 we review the sequential copying garbage collection. We start describing this work in Section 4 with our main idea: the delayed allocation method. A short discussion on work distribution is provided in 5. We continue with termination detection in Section 6 and we conclude in Section 7.

2 Design goals

We present the design goals for our parallel collector. The three major goals are efficiency, scalability and the preservation of the advantages of sequential copying garbage collection. These major goals are achieved via the following concrete goals:

1. Load balancing: Load balancing is always a crucial point in the efficiency of a parallel algorithm. Efficiency suffers if some of the processors are idle while the other processors perform the work.

2. Scalability: We would like the algorithm to achieve large speedup on today’s SMP machine, and also to allow scalability to a bigger number of processors in future SMP’s. One major consideration here is to avoid contention when accessing shared resources.

3. Compaction: We would like to preserve the major advantage of the sequential copying collector: the collection produces a compacted heap.

4. Locality of reference: An important goal in the design is to try and avoid cache misses as much as possible. A collector that incurs many cache misses cannot be considered efficient.

5. Avoid excessive synchronization: The parallel threads must synchronize while distributing the work between them and while accessing
mutual resources. However, it is desirable to keep the synchronization points as few as possible since performing any synchronized operation such as a compare and swap instruction (even without incurring any conflict) can be expensive. In our algorithm, we incur little more than once synchronized operation per copied object.

6. **Simplicity**: Finally, we believe that the design should be simple. A very complicated collector will probably not be used in practice.

Two remarks are in order. First, in many cases, there is a tradeoff between the various goals. For example, for load balancing we will usually prefer to cut the jobs to small pieces, but for small contention we would like to let the threads work on large jobs before they have to synchronize again. In any design, we must settle these tradeoffs, and we believe that a good design leaves as many open parameters as possible so that the algorithm can be adjusted to any specific local environment.

## 3 Sequential Copying Garbage Collection

In order to start discussing our ideas for parallel copying collection, let us review the steps in the sequential copying collector [20, 11, 3]:

1. Stop mutator threads;
2. Flip the roles of from-space and to-space;
3. Scan the roots in each mutator thread and also the global roots. For each object referenced by a root (child of a root):
   - (a) If this child is not yet copied then
     i. Copy child to to-space;
     ii. Write a forwarding pointer in (the from-space copy of) the child;
   - (b) Update the root pointer to point to the new copy of the child in to-space;
4. **Scan to-space**: For each child of an object in to-space:
   - (a) If this child is not yet copied then
     i. Copy child to to-space;
     ii. Write a forwarding pointer in the child;
   - (b) Update the pointer in the father object to point to the new replica of the child in to-space;
5. Reclaim from-space area;
6. Release mutator threads;
4 Parallel copying collection

The basic idea of the sequential algorithm is still used and we concentrate on extending this algorithm to parallel collection. A naive parallelization of the sequential algorithm would have each collector thread do part of the scan. However, this leads to a bottleneck on the to-space allocation pointer. Working with a single pointer is simple and elegant, but when several collector threads perform the copies, they will heavily compete on a single resource causing unacceptable contention. Other problems also arise. For example, we don’t want several collector threads to copy the same (popular) object several times, we have to distribute the parallel work carefully, etc. We start with the allocation problem and go on to the other problems in the following sections.

4.1 Previous solutions

Several previous systems tried to prevent contention on the to-space allocation pointer for each copy of an object. The first solution, used by Halstead [13] and Crammond [5] was to partition to-space into $n$ equal spaces, where $n$ is the number of processors, and let each processor allocate in its own private space. This completely solves the contention on allocation but has a major drawback (reported by Halstead): the allocation requests by the different processors are not even and thus one processor gets stuck on failing allocation when other processors have big empty spaces. Halstead suggested to ameliorate the behavior of the system by letting each collector allocate a “chunk” of memory and perform allocations inside the chunk privately. Namely, when a collector needs to copy an object to to-space, then it actually allocates a big area (a chunk), copies the object in hand, and keeps copying subsequent objects to this private area until there is no more room and a new area should be allocated.

This method, adopted by Miller and Epstein [19] following [18, 4] solves the contention conflict problem for to-space allocations since these allocations become much less frequent. However, a new problem arises: the fragmentation of to-space. Recall that one of the major benefits of a copying garbage collection is compaction of the heap. With this solution, we do not compact the heap through the collection.

To solve the fragmentation problem, Imai and Tick [15] suggested letting each processor manage several chunks, each used for a specific size of allocation. Typical sizes are powers of two, and objects that fall in between
these sizes (such as an object of size 5) are allocated on the chunk that uses the smallest power of 2 big enough to hold them (e.g., allocate 8 bytes to keep an object of 5 bytes). The waste of space in their scheme is at most half, and in practice much less. However, this scheme needs management of the chunks and it complicates the solution. Also, it does not completely overcome the fragmentation problem.

Flood et al [12] adopt a version of the chunk allocation solution called *local allocation buffers*. We remark that this kind of allocation has recently become common. As applications are multithreaded, some synchronization is required for allocation and using thread local allocation seems to be the best option. However, as we will claim, when allocating for the collector, more flexibility may be assumed as allocations may be delayed.

In what follows, we present a method in which the garbage collection outputs a heap with no fragmentation at all. Our solution, the *delayed allocation* method, is simpler than the Inai and Tick solution, and does not increase the contention on allocation.

### 4.2 Delayed allocation

The idea is to differentiate between regular allocation performed by the mutators and the special allocation that the collector needs. When a mutator allocates, the space must be assigned immediately to avoid delaying the mutator. However, the collector’s allocations may be delayed. In our scheme, a collector thread does not perform each allocation immediately when the original algorithm dictates a copy. Instead, the collector thread keeps an allocation log in which it records which copies should be performed. Whenever a copy of an object from *from-space* to *to-space* is needed, the collector thread adds a record to the allocation log in which it puts the *from-space* address of the object and the *to-space* (or root) address of the cell pointing to the object. Also, it updates the accumulated size of all objects mentioned in the allocation log. This single number is kept at the beginning of the log.¹

This accumulated size, i.e., the sum of all objects to be copied, is the space needed to apply the allocation log. When the accumulated size is big enough, e.g., a page, the collector actually applies the allocation log: it allocates the exact space needed for all the objects, and then it copies the objects.

¹One may choose to keep all sizes of all objects in the allocation records. This is a good idea if detecting the length of an object requires a few operations, and we do not want to read this length in the *from-space* area twice.
Note that there is no fragmentation at all since the allocated space in
*to-space* exactly matches the space needed to copy the objects mentioned in
the log. Also, the frequency of conflicts and synchronized operations does
not increase. Finally, big objects do not require special care, and they fall
naturally into the framework set by delayed allocation.

One may think that delayed allocation has a disadvantage in foiling
locality of reference. For each object we start by looking at its header and
only (somewhat) later we copy it as a whole. So if the header is evacuated
from the cache, we get an additional cache miss. However, fixing reasonable
parameters (similar to previous work), eliminates this problem. If the cache
is big enough to hold all copied objects in a chunk twice (once for *from-
space* and once for *to-space*) and also the allocation log itself, then we get
no additional cache misses. Setting the chunk size to around 1kb ensures
good behavior on most processors available today. In any case, one must
tune this parameter carefully.

We proceed with the next synchronization issue: the parallel access to
objects in *from-space*.

### 4.3 Synchronizing access to *from-space*

The parallel access to *from-space* is the second obstacle that has to be proper-
ly managed. It is possible that two collector threads will try to work on
the same *from-space* object, since they are scanning two different parents of
this object in parallel. We would like to stress that the contention on *from-
space* handling is of far lower likelihood than the contention on *to-space*
allocation. For the latter, any two collector threads copying any two objects
cause contention on *to-space* allocation. Whereas only two collector threads
that try to handle the very same object at the same time will face contention
on *from-space* handling. This has indeed been reported as a minor problem
in previous works. Hakstead [13] reports less than one conflict per second
(experienced with Concert Multilisp running on eight processors). This is
the reason why we don’t feel there is a need for an advanced mechanism
to handle these contentions. Our mechanism is simple (and standard) and
allows a good distribution of work between the collector threads.

The data structure we keep consists of two bits per object, the *work bit*
and the *done bit*, and also a separate list called the *parents log*. The done bit
indicates that the object was copied to *to-space*. This bit must also be used
in the sequential version of the algorithm. In some systems, it is possible to
tell whether a forwarding pointer was written in the header of the object,
and in this case, the done bit is not needed. In addition to the done bit (or the ability to tell whether a forwarding pointer has been written), we need an additional bit for our parallel version of the algorithm: the work bit. This bit indicates that the object is now being copied to to-space by some collector and there is no need to copy it again. At the start of a collection, the work bit and the done bit are clear at all objects. The done bit and the work bit are kept in the object header\(^2\).

The parents log contains records of parents whose pointers reference from-space and should be updated to reference the to-space copies. We will explain the need for the parents log later. Let us proceed with the algorithm.

Consider a collector thread that is scanning a pointer that references a from-space object. Either the pointer resides in to-space or it is a mutator root. The collector has to copy the referenced object into to-space if it has not yet been copied, and then update the pointer. The collector reads the work and done bits in the child. If the done bit is set, then the collector only needs to update the given pointer according to the forwarding pointer in the child. Another possibility is that the work bit is not set. In this case, the collector has to perform the actual copy of the child into to-space. To do this, the collector uses a synchronized operation (such as compare and swap) to set the work bit. We begin with describing the case that this operation succeeded and the collector is now responsible for copying the object. We will deal later (in Subsection 4.3.1 below) with the two similar cases that remain: The case that the collector failed to set the work bit (i.e., another processor won and is doing the copy) and the case that upon reading the bits of the child object, the collector found that the work bit was set but the done bit was not set.

So suppose the collector did set the work bit of the object. It then checks the size of the object and adds a record to the allocation log containing the location of the pointer and the address of the from-space object. Also, the collector adds the object length to the accumulated size of the objects registered in the allocation log and checks if it is time to do the actual allocation, i.e., if the total size of objects in the allocation log has grown big enough. If it is, the collector actually allocates the needed space and applies the records in the allocation log.\(^3\) Applying a record means: Copying the

\(^2\)It is probably not a good idea to keep these bits in a separate dense table, since such an implementation increases the chances of contention, thus incurring higher synchronization costs.

\(^3\)We remark that locality considerations dictate that the log should be applied from last recently written record to the most recently written record.
relevant object, setting the done-bit in the from-space copy, clearing the work-bit and done-bit in the to-space copy (so that they are ready for the next collection), and updating the parent pointer to reference the new copy in to-space.

4.3.1 The parents log

We now return to the case that the collector has a pointer to update, but the pointed-to object is being handled by another collector thread. One cannot let the collector wait till the other collector finishes the update of the child, since this option is not efficient and could lead to a deadlock. Instead, we use a global structure called the parents log in which the collector writes a request to later update the pointer. A record in the log contains the address of the pointer which should be updated and the address of the child in from-space. The log is global (rather than being associated with an object), and the collector threads apply the parents log when they cannot find any more objects to scan (usually, towards the end of the collection).

Synchronization to the parents log can be made negligible using buffering. Instead of updating the parents log each time a problematic pointer is traversed, the collector stores the parents log record in a local private buffer. When several records have been accumulated, it adds the buffer to the parents log in a synchronized manner. Thus, the parents log becomes a list of buffers, each of which, contains actual records of the parents log. Later, a collector applies the records in the log by removing a full buffer from the log and applying the records in the buffer. Synchronization is minimal since it occurs only when buffers are added or removed from the log. The size of the buffers can be set as a parameter, tuned by the behavior of the applications.

Parents log - a discussion. The parents log are processed when a collector thread cannot find more pointers to be scanned in to-space. This usually happens at a late stage of the collection when most of the objects in from-space have already been copied. In this stage of the collection most records in the parents log may be applied, as the done bits of most objects are set. However, in case a parents log record cannot be applied, we choose to re-enqueue the record and leave it in the parents log for future handling.

Another interesting issue is the worst case size of the parents log. In typical programs most objects have a low reference count, and thus, the chance of encountering a pointer whose referent is being handled by another collector thread concurrently is small. However, there may exist bad cases,
in which there is a popular object with a huge number pointers referencing it. From the time a collector thread first starts handling this object and until it sets the object’s done bit, all other pointers to this object, encountered by the collector threads, are put on the parents log. This may cause a large unbounded parents log.

If one wants to ensure that the parents log is bounded, then the following simple mechanism may be used. A new bit is employed per object, signifying that a pointer to it appears on the parents log. This bit is initially clear and it is set by a thread that inserts a related record to the parents log. Whenever a thread notices that one of the objects in its allocation log is responsible for a record in the parents log, then it acts as if the space threshold has been met. Namely, it allocates space and applies the records of its allocation log. A thread notices such an incident by examining these bits “once in a while”. For example, after handling 10 to-space pointers.

4.3.2 Specifying the algorithm

We summarize by specifying a pseudo code of the algorithm for handling a given pointer \( p \) in to-space or a root pointer that references an object in from-space.

If done bit of \(*p\) is set then

Update \( p \) using the forwarding pointer

Else if work bit of \(*p\) is set then

Use CAS (compare and swap) to set the work bit

If CAS succeeded then

Insert a record to the allocation log with location of

\( p \) and size of the \(*p\).

Add size of object to accumulated size.

If accumulated size > threshold then

Allocate accumulated size in to-space

For each pointer in allocation log

Copy referenced object to to-space

Insert a forwarding address to the object

Set object’s done bit

Update pointer to reference the new location

Else // CAS failed

Insert a record with parent and child location

to parents log
Else  // work bit set but done bit clear
  Insert a record with parent and child location
  to parents log

4.4 Heap management for the application

Garbage collection is tightly coupled with the heap manager. Note that our
method for to-space allocations during garbage collection is inappropriate for
managing the heap allocation by the mutators. Mutator allocations cannot
be delayed without delaying the mutator. Thus, we adopt Halstead’s idea
of memory-chunks (or thread local allocation) for application allocation.

5 Work distribution

Load balancing is one of the more important issues in making parallel im-
plementations run faster. Letting one processor do the work while other
processors are idle does not fully utilize a multiprocessor machine. Imai and
Tick [15] were the first to take explicit care for balancing the load of a par-
allel collector, and Endo et. al. [10] provided an enlightening measurements
showing the strong influence of load balancing on efficiency\textsuperscript{4}. Flood et al
[12] have adopted the queue stealing method of [10] for load balancing. We
believe the methods discussed in those two works are good and should be
adopted. The idea is that list of tasks are kept locally and may be stolen by
other collector threads.

6 Terminating the collection

When do the collector threads know that the collection has terminated?
Termination occurs when all the heap has been scanned, all live objects
have been copied and all pointers have been updated to point into the to-
space area. In practice, this means that the collector threads finish all jobs
in the job lists, and finish applying all records in the parents log.

A collector can check that the job lists are empty and that the parents log
is empty, but it must also check that all the other collector threads are idle
\begin{footnote}
Endo et. al. implemented a mark & sweep algorithm. In a mark and sweep algorithm
the collector marks all live objects, and later scans the whole heap and reclaims (sweeps)
unmarked objects. Note that although this is not a copying algorithm, this algorithm also
scans all live objects, and thus has similar behavior. See [16] for a detailed description of
mark & sweep algorithms.
\end{footnote}
and not producing more work to be done. Furthermore, the check must be atomic since another collector thread may write a new entry to the job lists, and later become idle. The issue of termination detection is error prone. In fact, a previous solution ([10], Section 4.2 there), for detecting termination in a parallel mark & sweep collector, has a flaw which we shortly describe below.

Let us first recall the termination detection proposed in [10]. The data structure consists of a global flag called the detection flag initially cleared, and a flag for each collector thread called the idle bit initially cleared.

To support termination detection the collector threads maintain their idle bit as follows. Whenever the thread is not working, its idle bit is set. In particular, a thread sets its idle bit when it finishes scanning its own areas, and has to look for a new area to scan. It then scans the lists to look for a job. Once it detects a job candidate, it clears the idle bit and then it “competes” on the job by performing a synchronized operation (e.g., compare and swap) trying to remove the job from its tasks list. If the collector fails to obtain the job, it sets the idle bit again and continues the search. Finally, to support the termination detection, the collector threads also perform the following operation: whenever a collector thread adds a record (or buffer) to the tasks list then before the add operation, it sets the detection flag. Intuitively, the detection flag is set to indicate that there is activity in the system and termination has not been reached yet.

A collector starts termination detection if the job market is empty. To check termination, the thread clears the detection flag. It then goes over all task lists to verify that they are empty and goes over all other threads to check that they are idle. Next, it checks that the detection flag is still cleared, and if all the above hold then it decides that termination was detected.

We now argue that this detection mechanism is not correct. The problem is that even if there is an activity in the system which causes the detection flag to be set, at a later time, another collector thread may start detecting termination and clear the flag just before the first detector looks at the flag again. Thus, the second detector misleads the first detector to think that the flag was not set throughout the detection, and the first collector terminates erroneously.
7 Conclusions

We introduced a design for a parallel copying garbage collector, which completely eliminates fragmentation, and is nevertheless efficient, low on synchronization, and simple. Our collector distributes the work with low synchronization overhead and has an efficient termination detection mechanism.
