Abstract

Inductive learning is based on inferring a general rule from a finite data set and using it to label new data. In transduction one attempts to solve the problem of using a labeled training set to label a set of unlabeled points, which are given to the learner prior to learning. Although transduction seems at the outset to be an easier task than induction, there have not been many provably useful algorithms for transduction. Moreover, the precise relation between induction and transduction has not yet been determined. The main theoretical developments related to transduction were presented by Vapnik more than twenty years ago. One of Vapnik's basic results is a rather tight error bound for transduction based on exact computation of the hypergeometric tail. While being tight, this bound is given implicitly via a computational routine. Our first contribution is a somewhat looser but explicit characterization of a slightly extended PAC-Bayesian version of Vapnik's transductive bound. This characterization is obtained using concentration inequalities for the tail of sums of random variables obtained by sampling without replacement. We then derive error bounds for compression schemes such as (transductive) support vector machines and for transduction algorithms based on clustering. The main observation used for deriving these new error bounds and algorithms is that the unlabeled test points, which in the transductive setting are known in advance, can be used in order to construct useful data dependent prior distributions over the hypothesis space.

1. Introduction

The bulk of work in Statistical Learning Theory has dealt with the inductive approach to learning. Here one is given a finite set of labeled training examples, from which a rule is inferred. This rule is then used to label new examples. As pointed out by Vapnik (e.g. Vapnik, 1998) in many realistic situations one actually faces an easier problem where one is given a training set of labeled examples, together with an unlabeled set of points which needs to be labeled. In this transductive setting, one is not interested in inferring a general rule, but rather only in labeling this unlabeled set as accurately as possible. One solution
is of course to infer a rule as in the inductive setting, and then use it to label the required
points. However, as pointed out in (Vapnik, 1982, 1998), it makes little sense to solve what
appears to be an easier problem by ‘reducing’ it to a more difficult one. While there are
currently no formal results stating that transduction is indeed easier than induction\(^1\) it is
plausible that the relevant information carried by the test points can be incorporated into an
algorithm, potentially leading to superior performance. Since in many practical situations
we are interested in evaluating a function only at some points of interest, a major open
problem in statistical learning theory is to determine precise relations between induction
and transduction.

In this paper we present several general error bounds for transductive learning.\(^2\) We
also present a general technique for establishing error bounds for transductive learning al-
gorithms based on compression and clustering. Our bounds can be viewed as extensions of
McAllester’s PAC-Bayesian framework (McAllester, 1999a, 2003a,b) to transductive learn-
ing. The main advantage of using the PAC-Bayesian approach in transduction, as opposed
to induction, is that here prior beliefs on hypotheses can be formed based on the unlabeled
test data. This flexibility allows for the choice of “compact priors” (with small support)
and therefore, for tight bounds. We use the established bounds and provide tight error
bounds for “compression schemes” such as (transductive) SVMs and transductive learning
algorithms based on clustering. While precise relations between induction and transduc-
tion remain a major challenge, our new bounds and technique offer some new insights into
transductive learning.

The problem of transduction was formulated as long ago as 1982 in Vapnik’s classic
book (Vapnik, 1982), where the precise setting was formulated, and some implicit error
bounds were derived.\(^3\) In recent years the problem has been receiving an increasing amount
of attention, due to its applicability to many real world situations. A non-exhaustive list of
recent contributions includes Vapnik (1998), Joachims (1999), Bennett and Demiriz (1998),
Demiriz and Bennett (2000), Wu et al. (1999), Lanckriet et al. (2002), Blum and Langford
(2003). Most of this work (with the exception of Vapnik (1998) and Lanckriet et al. (2002))
has dealt with algorithmic issues, rather than with performance bounds. Implicit perfor-
mance bounds, in the spirit of (Vapnik, 1982, 1998) have recently been presented in (Blum
and Langford, 2003). We mention these results again later in Section 2.2.

We present explicit PAC-Bayesian bounds for a transductive setting that considers sam-
ping without replacement of the training set from a given ‘full sample’ of unlabeled points.
This setting is proposed by Vapnik and it turns out that error bounds for learning algo-
rithms, within this setting, imply the same bounds within another setting which may appear
more practical (See Section 2.1 and Theorem 2 for details). Sampling without replacement
of the training set leads to the training points being dependent (see Section 2.1 for details).
Our first goal is to provide uniform bounds on the deviation between the training error
and the test error. To this end, we study two types of bounds that utilize two different

---

1. There may be various ways to state this in a meaningful manner. Essentially, we would like to know if
   for some learning problems a particular transductive algorithm can achieve better performance than any
   inductive algorithm, where performance may be characterized by learning rates and/or computational
   complexity.
2. In the paper we use the terms ‘error bound’ and ‘risk bound’ interchangeably. Strictly speaking, the
   term ‘generalization bound’ is not appropriate in the transductive setting.
3. Vapnik refers to transduction also as “estimating the values of a function at given points of interest”.

---

2
bounding techniques. The first approach is based on an observation made in Hoeffding’s classic paper (Hoeffding, 1963), recently alluded to in Lugosi (2003). As pointed out by Hoeffding (1963), the sampling without replacement problem can be reduced to an equivalent problem involving independent samples, for which standard techniques suffice. We refer to this approach as the ‘reduction to independence’ setting. A second approach involves derivations of large deviation bounds for sampling without replacement such as those developed in (Serfling, 1974, Vapnik, 1998, Hush and Scovel, 2003, Dembo and Zeitouni, 1998). We refer to such bounds as ‘direct’. We consider these two approaches in Section 3.1 and 3.2, respectively. Using these two approaches we derive general PAC-Bayesian bounds for transduction. It turns out that the direct bounds lead to tighter and more explicit learning curves for transduction.

We then show how to utilize PAC-Bayesian transductive bounds to derive error bounds for specific learning schemes. In particular, we show how to choose priors, based on the given unlabeled data, and derive bounds for “compression schemes” and learning algorithms based on clustering. Compression schemes are algorithms that select the same hypothesis using only a subset of the training data. The main example of a compression scheme is a (transductive) Support Vector Machine (SVM). The compression level achieved by such schemes typically depends on the (geometric) complexity of the learning problem at hand, which sometimes does not allow for significant compression. A stronger type of compression can be often achieved using clustering. A natural approach in the context of transduction (and semi-supervised learning) is to apply a clustering algorithm over the set of all available (unlabeled) points and then to use the labeled points to determine the classifications of points in the resulting clusters. For this scheme we prove a rather tight error bound by utilizing an appropriate prior in our transductive PAC-Bayesian bounds. For practical applications a similar but tighter result is obtained by using the implicit bounds of Vapnik (1998).

2. Problem Setup and Vapnik’s Basic Results

2.1 Problem Setup

The problem of transduction can be informally described as follows. A learner is given a set of labeled examples \( \{(x_1, y_1), \ldots, (x_m, y_m)\} \), \( x_i \in \mathcal{X}, y_i \in \mathcal{Y} \), and a set of unlabeled points \( \{x_{m+1}, \ldots, x_{m+u}\} \). Based on this data, the objective is to label the unlabeled points. We consider the setting proposed by Vapnik (1998, Chap. 8), which for simplicity is described in the context of binary classification.\(^4\) Let \( \mathcal{H} \) be a set of binary hypotheses consisting of functions from the input space \( \mathcal{X} \) to \( \mathcal{Y} = \{\pm 1\} \). Let \( \mu(x, y) \) be any distribution over \( \mathcal{X} \times \mathcal{Y} \). For each \( h \in \mathcal{H} \) and a set \( Z = x_1, \ldots, x_{|Z|} \) of samples define

\[
R_h(Z) \triangleq \frac{1}{|Z|} \sum_{i=1}^{|Z|} \mathbb{E}_{\mu(y|x_i)} \{\ell(h(x_i), y)\} = \frac{1}{|Z|} \sum_{i=1}^{|Z|} \int_{y \in \mathcal{Y}} \ell(h(x_i), y) d\mu(y|x_i),
\]

where, unless otherwise specified, \( \ell(\cdot, \cdot) \) is the 0/1 loss function. Vapnik (1998) considers the following two transductive “protocols”.

\(^4\) Note that some of our results hold for general bounded loss functions.
**Setting 1:**

(i) A full sample $X_{m+u} = \{x_1, \ldots, x_{m+u}\}$ consisting of arbitrary $m + u$ points is given.\(^5\)

(ii) We then choose uniformly at random the training sample $X_m \subseteq X_{m+u}$ and receive its labels $Y_m$ where the label $y$ of $x$ is chosen according to $\mu(y|x)$; the resulting training set is $S_m = (X_m, Y_m)$ and the remaining set $X_u$ is the unlabeled (test) sample, $X_u = X_{m+u} \setminus X_m$.

(iii) Using both $S_m$ and $X_u$ we select a classifier $h \in \mathcal{H}$. The quality of $h$ is measured by $R_h(X_u)$.

**Setting 2:**

(i) We are given a training set $S_m = (X_m, Y_m)$ selected i.i.d according to $\mu(x, y)$.

(ii) An independent test set $S_u = (X_u, Y_u)$ of $u$ samples is then selected in the same manner.

(iii) We are required to choose our best $h \in \mathcal{H}$ based on $S_m$ and $X_u$ so as to minimize

$$R_{m,u}(h) \triangleq \int \frac{1}{u} \sum_{i=m+1}^{m+u} \ell(h(x_i), y_i) \, d\mu(x_1, y_1) \cdots d\mu(x_{m+u}, y_{m+u}).$$

**Remark 1** Notice that the choice of the sub-sample $X_m$ in Setting 1 is equivalent to sampling $m$ points from $X_{m+u}$ uniformly at random without replacement. This leads to the samples being dependent. Also, Setting 1 concerns an “individual sample” $X_{m+u}$ and there are no assumptions regarding its underlying source. The only element of chance in this setting is the random choice of the training set from the full sample.

Setting 2 may appear more applicable in some practical situations than Setting 1. However, derivation of theoretical results can be easier within Setting 1. The following useful theorem (Theorem 8.1 in Vapnik (1998)) relates the two transduction settings. For completeness we present Vapnik’s proof in the appendix.

**Theorem 2 (Vapnik)** If for some learning algorithm choosing an hypothesis $h$ it is proved within Setting 1 that with probability at least $1 - \delta$, the deviation between the risks $R_h(X_m)$ and $R_h(X_u)$ does not depend on the composition of the full sample and does not exceed $\varepsilon$, then with the same probability, in Setting 2 the deviation between $R_h(X_m)$ and the risk given by formula (2) does not exceed $\varepsilon$.

**Remark 3** The learning algorithm in Theorem 2 is implicitly assumed to be deterministic. The theorem can be extended straightforwardly to the case where the algorithm is randomized and chooses an hypothesis $h \in \mathcal{H}$ randomly, based on $S_m \cup X_u$. A particular type of randomization is the one used by Gibbs algorithms, as discussed in Section 4.1.

\(^5\) The original Setting 1, as proposed by Vapnik, discusses a full sample whose points are chosen independently at random according to some source distribution $\mu(x)$. 

4
Remark 4 The basic quantity of interest in Setting 2 is \( R_{m,u}(h) \) defined in (2). Assuming \( h \) is selected based on the sample \( S_m \cup X_u \), one is often interested in its expectation over a random selection of this sample. In inductive learning, one considers the sample \( S_m \) and a single new point \((x, y)\), and the average is taken with respect to \( S_m \cup \{X\} \). It should be noted that the random variable \( R_{m,u}(h) \) is ‘more concentrated’ around its mean than the random variable \( \ell(h(x), y) \) corresponding to a single new point \((x, y)\), and this it is perhaps not surprising that we should expect transduction to lead to tighter bounds in Setting 2.

In view of Theorem 2 we restrict ourselves in the sequel to Setting 1. Also, for simplicity we focus on the case where there exists a deterministic target function \( \phi : \mathcal{X} \rightarrow \mathcal{Y} \), so that \( y = \phi(x) \) is a fixed target label for \( x \); that is, \( \mu(\phi(x)|x) = 1 \) (there is no requirement that \( \phi \in \mathcal{H} \)). Note that it is possible to extend our results to the the general case of stochastic targets \( y \sim \mu(y|x) \).

We make use of the following quantities, which are all instances of (1). The quantity \( R_h(X_{m+u}) \) is called the full sample risk of the hypothesis \( h \), \( R_h(X_u) \) is referred to as the transduction risk (of \( h \)), and \( R_h(X_m) \) is the training error (of \( h \)). Note that in the case where our target function \( \phi \) is deterministic,

\[
R_h(X_m) = \frac{1}{m} \sum_{i=1}^{m} \mathbb{E}_{\mu(y|x_i)} \{ \ell(h(x_i), y) \} = \frac{1}{m} \sum_{i=1}^{m} \ell(h(x_i), \phi(x_i)).
\]

Thus, \( R_h(X_m) \) is the standard training error denoted interchangeably by \( \hat{R}_h(S_m) \). It is important to observe that while \( R_h(X_{m+u}) \) is not a random variable, both \( R_h(X_m) \) and \( R_h(X_u) \) are random variables, due to the random selection of the samples \( X_m \) from \( X_{m+u} \).

While our objective in transduction is to achieve small error over the unlabeled sample (i.e. to minimize \( R_h(X_u) \)), we find that it is sometimes easier to derive error bounds for the full sample risk. The following simple lemma translates an error bound on \( R_h(X_{m+u}) \), the full sample risk, to an error bound on the transduction risk \( R_h(X_u) \).

**Lemma 5** For any \( h \in \mathcal{H} \) and any \( C \)

\[
R_h(X_{m+u}) \leq \hat{R}_h(S_m) + C \iff R_h(X_u) \leq \hat{R}_h(S_m) + \frac{m+u}{u} \cdot C.
\]  

**Proof:** For any \( h \)

\[
R_h(X_{m+u}) = \frac{mR_h(X_m) + uR_h(X_u)}{m+u}.
\]  

Substituting \( \hat{R}_h(S_m) \) for \( R_h(X_m) \) in (4) and then substituting the result for the left-hand side of (3) we get

\[
R_h(X_{m+u}) = \frac{m\hat{R}_h(S_m) + uR_h(X_u)}{m+u} \leq \hat{R}_h(S_m) + C.
\]

The equivalence (3) is now obtained by isolating \( R_h(X_u) \) on the left-hand side. \( \Box \)

**Remark 6** In applications of Lemma 5, the term \( C = C(m) \) is typically a function \( m \) (and of some of the other problem parameters such as \( \delta \)). In meaningful bounds \( C(m) \rightarrow 0 \) with \( m \rightarrow \infty \). Observe that in order for the bound on \( R_h(X_u) \) to converge it must be that \( u = \omega(mC(m)) \).
Consider a hypothesis class $H$. In the context of transduction, we are only interested in labeling the test set $X_u$, which is given in advance. Thus, we may in principle regard hypotheses in $H$ which label $X_{m+u}$ identically as belonging to the same equivalence class. Since for fixed values of $m$ and $u$ the number of equivalence classes is finite (in the case of binary hypotheses, it is at most $2^{m+u}$) we may, without loss of generality, restrict ourselves to a finite hypothesis class (see, for example Vapnik, 1998, Sec. 8.5). Note that this freedom is not available in the inductive setting, where the test set is not known in advance.

2.2 Vapnik’s Implicit Bounds

Fix some hypothesis $h \in H$ and suppose that $h$ makes $k_h$ errors on the full sample (i.e. $k_h = (m + u)R_h(X_{m+u})$). Consider a random choice of the training set $S_m$ from the full sample, and let $B(r, k_h, m, u)$ be the probability that $h$ makes exactly $r$ errors over the training set $S_m$. This probability is by definition the hypergeometric distribution, given by

$$B(r, k_h, m, u) \triangleq \frac{{k_h \choose r} \frac{(m + u - k_h)}{(m - r)}}{m + u}.$$ 

Since $m$ and $u$ are fixed, throughout this discussion we abbreviate $B(r, k_h) \triangleq B(r, k_h, m, u)$.

Define

$$C(\varepsilon, k_h) \triangleq \Pr\{R_h(X_u) - R_h(X_m) > \varepsilon\} = \Pr\left\{\frac{k_h - r}{u} - \frac{r}{m} > \varepsilon\right\} = \sum_r B(r, k_h),$$

where the summation is over all values of $r$ such that $\max\{k_h - u, 0\} \leq r \leq \min\{m, k_h\}$ and

$$\frac{k_h - r}{u} - \frac{r}{m} > \varepsilon.$$ \hspace{1cm} (5)

Define

$$\Gamma(\varepsilon) \triangleq \max_k C\left(\sqrt{\frac{k}{m + u}} \cdot \varepsilon, k\right).$$ \hspace{1cm} (6)

We now state Vapnik’s implicit bound for transduction. The bound is slightly adapted to incorporate a prior probability over $H$ (the original bound deals with a uniform prior). Also, the original bound in Vapnik (1982) is two-sided and the following theorem is one-sided.\(^6\)

**Theorem 7 (Vapnik 1982)** Let $\delta$ be given, let $p$ be a prior distribution over $H$, and let $\varepsilon^*(h)$ be the minimal value of $\varepsilon$ that satisfies $\Gamma(\varepsilon) \leq p(h)\delta$. Then, with probability at least $1 - \delta$, for all $h \in H$,

$$R_h(X_u) - R_h(X_m) < \varepsilon^*(h).$$ \hspace{1cm} (7)

\(^6\) Specifically, in the original bound of (Vapnik, 1982) the two-sided condition $|\frac{k_h - r}{u} - \frac{r}{m}| > \varepsilon$ is used instead of condition (5).
Proof: Using the union bound we have,

\[ Q = \Pr \left\{ \exists h \in \mathcal{H} : \frac{R_h(X_u) - R_h(X_m)}{\sqrt{R_h(X_{m+u})}} > \varepsilon^*(h) \right\} \]

\[ = \Pr \left\{ \exists h \in \mathcal{H} : R_h(X_u) - R_h(X_m) > \sqrt{R_h(X_{m+u})\varepsilon^*(h)} \right\} \]

\[ = \Pr \left\{ \exists h \in \mathcal{H} : R_h(X_u) - R_h(X_m) > \sqrt{\frac{k_h}{m+u} \varepsilon^*(h)} \right\} \]

\[ \leq \sum_{h \in \mathcal{H}} C \left( \sqrt{\frac{k_h}{m+u}} \varepsilon^*(h), k_h \right) \] \hspace{1cm} (8)

\[ \leq \sum_{h \in \mathcal{H}} \Gamma(\varepsilon^*(h)) \]

\[ \leq \sum_{h \in \mathcal{H}} p(h) \delta = \delta. \]

Note: The convention \( \frac{R_h(X_u) - R_h(X_m)}{\sqrt{R_h(X_{m+u})}} = 0 \) is used whenever \( R_h(X_u) = R_h(X_m) = R_h(X_{m+u}) = 0. \)

It is not hard to convert the bound (7) to the “standard” form (i.e. expressed as empirical error plus some complexity term). Squaring both sides of (7) and then substituting \( \frac{m}{m+u} R_h(X_m) + \frac{u}{m+u} R_h(X_u) \) for \( R_h(X_{m+u}) \) we get a quadratic inequality where the “unknown” variable is \( R_h(X_u) \). Solving for \( R_h(X_u) \) yields the following result (as in Vapnik, 1998, Equation (8.15)).

**Corollary 8** Under the conditions of Theorem 7,

\[ R_h(X_u) \leq R_h(X_m) + \frac{\varepsilon^*(h)^2 u}{2(m+u)} + \varepsilon^*(h) \sqrt{R_h(X_m) + \left( \frac{\varepsilon^*(h) u}{2(m+u)} \right)^2}. \]

Note that a related result has recently been presented in (Blum and Langford, 2003).

**Remark 9** The bound of Corollary 8 is rather tight. Possible sources of slackness are only introduced through the utilization of the union bound in (8) and the definition of \( \Gamma \) in (6). However, note that \( \varepsilon^*(h) \) is a complicated implicit function of \( m, u, p(h) \) and \( \delta \) leading to a bound that is difficult to interpret and (as noted also by Vapnik) must be tabulated by a computer in order to be used.

### 3. Concentration Inequalities for Sampling without Replacement

In this section we present several concentration inequalities that will be used in Section 4 to develop PAC-Bayesian bounds for transduction. As discussed in Section 2 (see Remark 1), sampling without replacement leads to dependent data, precluding direct application of standard large deviation bounds devised for independent samples. Here we present several concentration inequalities for sampling without replacement.
3.1 Inequalities Based on Reduction to Independence

Even though sampling without replacement leads to dependent samples, Hoeffding (1963) pointed out a simple procedure to transform the problem into one involving independent data. While this procedure leads to non-trivial bounds, we point out in Section 3.2 that it involves some loss in tightness.

Lemma 10 (Hoeffding) Let \( C = \{c_1, \ldots, c_N\} \) be a finite set with \( N \) elements, let \( \{X_1, \ldots, X_m\} \) be chosen uniformly at random with replacement from \( C \), and let \( \{Z_1, \ldots, Z_m\} \) be chosen uniformly at random without replacement from \( C \). Then, for any continuous and convex real-valued function \( f(x) \),

\[
E f(\sum_{i=1}^{m} Z_i) \leq E f(\sum_{i=1}^{m} X_i).
\]

Lemma 10 can be used in order to generate standard exponential bounds, as in (Hoeffding, 1963). We first introduce some notation which will be used in the sequel. Let \( \nu \) and \( \mu \) be two real numbers in \([0, 1]\). We use the following definitions for the binary entropy and binary KL-divergence, respectively.

\[
H(\nu) \triangleq -\nu \log \nu - (1 - \nu) \log(1 - \nu),
\]

\[
D(\nu \| \mu) \triangleq \nu \log \frac{\nu}{\mu} + (1 - \nu) \log \frac{1 - \nu}{1 - \mu}.
\]

Theorem 11 (Hoeffding) Let \( C = \{c_1, \ldots, c_N\} \) be a finite set of non-negative bounded real numbers, \( c_i \leq B \), and set \( \bar{c} = (1/m) \sum_{i=1}^{m} c_i \). Let \( Z_1, \ldots, Z_m \), be random variables obtaining their values by sampling \( C \) uniformly at random without replacement. Set \( Z = (1/m) \sum_{i=1}^{m} Z_i \). Then, for any \( \varepsilon \leq 1 - \bar{c}/B \),

\[
\Pr\{Z - \bar{E}Z \geq \varepsilon\} \leq \exp\left\{-mD\left(\frac{\bar{c}}{B} + \varepsilon \left\| \frac{\bar{c}}{B} \right\|\right)\right\}
\]

\[
\leq \exp\left\{-\frac{2m\varepsilon^2}{B^2}\right\}
\]

Similar bounds hold for \( \Pr\{\bar{E}Z - Z \geq \varepsilon\} \).

The key to the proof Theorem 11 is the application of Lemma 10 with \( f(\sum_i Z_i) = \exp\{\sum_i (Z_i - \bar{E}Z_i)\} \) and the utilization of the Chernoff-Hoeffding bounding technique (see Hoeffding, 1963, for the details).

3.2 Sampling Without Replacement - Direct Inequalities

In this section we consider approaches which directly establish exponential bounds for sampling without replacement. As opposed to Vapnik’s results (Vapnik, 1998) which provide tight but implicit bounds, we aim at bounds which depend explicitly on all parameters of interest. Note that the bound of Theorem 11 does not depend on all the parameters (in particular, the population size \( N \) does not appear and clearly, small population size should affect the convergence rate). One may expect that bounds developed directly for sampling without replacement should be tighter than those based on reduction to independence. The
reason for this is as follows. Assume, we have sampled \( k \) out of \( N \) points without replacement. The next point is to be sampled from a set of \( N - k \) rather than \( N \) points, which would be the case in sampling with replacement (where the samples are independent). The successive reduction in the size of the sampled set reduces the ‘randomness’ of the newly sampled point as compared to the independent case. This intuition is at the heart of Serfling’s (Serfling, 1974) improved bound, which is quoted next. This result holds for general bounded loss functions and is established by a careful utilization of martingale techniques combined with Chernoff’s bounding method.

**Theorem 12 (Serfling (1974))** Let \( C = \{c_1, \ldots, c_N\} \) be a finite set of bounded real numbers, \(|c_i| \leq B\). Let \( Z_1, \ldots, Z_m \), be random variables obtaining their values by sampling \( C \) uniformly at random without replacement. Set \( Z = \frac{1}{m} \sum_{i=1}^{m} Z_i \). Then,

\[
\Pr\{Z - EZ \geq \varepsilon\} \leq \exp\left\{-\left(\frac{2m\varepsilon^2}{B^2}\right)\left(\frac{N}{N - m + 1}\right)\right\},
\]

and similarly for \( \Pr\{EZ_m - Z_m \geq \varepsilon\} \).

Compared to the bound of Theorem 11, the bound in (11) is always tighter than Hoeffding’s second bound (10) when \( N/(N - m + 1) > 1 \) (i.e. when \( m > 1 \)). When applied to our transduction setup (see Section 4.1) we take \( N = m + u \) and the advantage is maximized when \((m + u)/(u + 1)\) is maximized. Thus, considering only the convergence rate obtained by sampling without replacement one may expect that the fastest rates should be obtained when \( u \) assumes the smallest possible value (e.g. \( u = 1 \)) and not surprisingly, the advantage over the bound of Theorem 11 vanishes as \( u \to \infty \).

In the case where the \( c_i \) are binary variables, the bound in Theorem 12 can be improved, by using a proof based on a counting argument. The following theorem and proof is based on a simple consequence of Lemma 2.1.33 in (Dembo and Zeitouni, 1998).

**Theorem 13** Let \( C = \{c_1, \ldots, c_N\}, c_i \in \{0, 1\}, \) be a finite set of binary numbers, and set \( \tilde{c} = (1/N) \sum_{i=1}^{N} c_i \). Let \( Z_1, \ldots, Z_m \), be random variables obtaining their values by sampling \( C \) uniformly at random without replacement. Set \( Z = (1/m) \sum_{i=1}^{m} Z_i \) and \( \beta = m/N \). Then, if \( \varepsilon \leq \min\{1 - \tilde{c}, \tilde{c}(1 - \beta)/\beta\} \),

\[
\Pr\{Z - EZ > \varepsilon\} \leq \exp\left\{-mD(\tilde{c} + \varepsilon\|\tilde{c}) - (N - m) D\left(\tilde{c} - \frac{\beta\varepsilon}{1 - \beta}\|\mu\right) + 7 \log(N + 1)\right\}.
\]

**Proof:** Denote by \( N_0 \) and \( N_1 \) the number of appearances in \( C \) of \( c_i = 0 \) and \( c_i = 1 \), respectively. Let \( m_0 \) and \( m_1 \) be integers \( 0 \leq m_0, m_1 \leq m \), such that \( m_0 + m_1 = m \). The probability of observing \( m_1 \) appearances of ‘1’ (and thus \( m_0 \) appearances of ‘0’) in a random sub-sample selected without replacement is the number of \( m \)-tuples resulting in \( m_1(0\text{'s}) \) appearances of \( 0(1) \) in the subsample, divided by the overall number of \( m \)-tuples,

\[
\Pr\left\{\sum_{i=1}^{m} Z_i = m_1\right\} = \frac{\binom{N_1}{m_1}\binom{N_0}{m_0}}{\binom{N}{m}}.
\]

---

8. The second condition, \( \varepsilon \leq \tilde{c}(1 - \beta)/\beta \), simply guarantees that the number of ‘ones’ in the sub-sample does not exceed their number in the original sample.
Setting $\mu = \bar{c}$, the probability that $Z = \left(1/m\right) \sum_{i=1}^{m} Z_i$ is greater than $\nu \triangleq \mu + \varepsilon = m_1/m$ (for some natural number $m_1$) is then given by

$$\Pr\left\{ \frac{1}{m} \sum_{i=1}^{m} Z_i > \nu \right\} = \sum_{m_1 = \lfloor m\nu \rfloor}^{m} \frac{(N_1 \choose m_1) (N_0 \choose m_0)}{(N \choose m)}.$$ 

Using the Stirling bound we have that

$$\max_{1 \leq m \leq N} \left| \log \left( \frac{N}{m} \right) - NH \left( \frac{m}{N} \right) \right| \leq 2 \log(N + 1).$$

We thus find that

$$\Pr\left\{ \frac{1}{m} \sum_{i=1}^{m} Z_i > \nu \right\} \leq \sum_{m_1 = \lfloor m\nu \rfloor}^{m} \exp \left\{ N_0 H \left( \frac{m_0}{N_0} \right) + N_1 H \left( \frac{m_1}{N_1} \right) - NH \left( \frac{m}{N} \right) + 6 \log(N + 1) \right\}$$

$$= \sum_{m_1 = \lfloor m\nu \rfloor}^{m} \exp \left\{ -mD(\nu\|\mu) - (N - m)D \left( \frac{\mu - \beta \nu}{1 - \beta} \| \mu \right) + 6 \log(N + 1) \right\}.$$ 

The claim is concluded by upper bounding the sum by the product of the number of terms in the sum and the maximal term. It is easy to verify that the maximal summand is attained at $\nu = \mu$. Assuming that $\nu > \mu$, and using the convexity of $D(\nu\|\mu)$ with respect to $\nu$, we conclude that the largest contribution to the sum is attained at $m_1 = m\nu$, yielding the bound

$$\Pr\left\{ \frac{1}{m} \sum_{i=1}^{m} Z_i > \nu \right\} \leq m(1 - \nu) \exp \left\{ -mD(\nu\|\mu) - (N - m)D \left( \frac{\mu - \beta \nu}{1 - \beta} \| \mu \right) + 6 \log(N + 1) \right\}$$

$$\leq \exp \left\{ -mD(\nu\|\mu) - (N - m)D \left( \frac{\mu - \beta \nu}{1 - \beta} \| \mu \right) + 7 \log(N + 1) \right\},$$

which establishes the claim upon setting $\nu = \bar{c} + \varepsilon$. \qed

Note that the proof of the last bound does not rely on the Chernoff-Hoeffding bounding technique as used in (Hoeffding, 1963) and in many other derivations, but rather on a direct counting argument.

**Remark 14** We are aware of another concentration inequality for sampling without replacement, which also applies to binary variables. This inequality, by Hush and Scovel (2003), is an extension of a result by Vapnik (1998, Sec. 4.13). While Vapnik’s result concerns the case $m = N/2$ ($u = m$ in the transduction setup), the result in (Hush and Scovel, 2003) considers the general case of arbitrary $m$ and $N$. The transduction bound we obtain using the concentration inequality in (Hush and Scovel, 2003) is more complex but qualitatively the same as the bound of Corollary 21 that we later present. We therefore omit this bound.
4. PAC-Bayesian Transduction Bounds

In this section we present general error bounds for transductive learning. Our bounds can be viewed as extensions of McAllester’s PAC-Bayesian inductive bounds in (McAllester, 1999b, 2003a,b). In Section 4.1 we focus on simple randomized learning algorithms which are typically referred to as ‘Gibbs algorithms’. Then in Section 4.2 we consider a standard deterministic setting. In the case of binary classification the bounds for deterministic learning are comparable to Vapnik’s bounds presented in Section 2.2. Unlike the implicit but tight PAC-Bayesian bound of Theorem 7 (and Corollary 8), the new bounds are somewhat looser but explicit.

4.1 Bounds for Transductive Gibbs Learning

We present two bounds. The first is a rather immediate extension of the bound (6) in McAllester (2003b), using a reduction to independence, as discussed in Section 3.1. The second bound is based on the ‘direct approach’ and is considerably tighter in many cases of interest.

Within the original inductive setting, the selection of the prior distribution \( p \) in the PAC-Bayesian bounds must be made prior to observing the data. As we later show, in the present transductive setting it is possible to obtain much more compact (and effective) priors by first observing the full input sample \( X_{m+u} \) and using it to construct a prior \( p = p(X_{m+u}) \). However, as shown in (McAllester, 2003a), under certain conditions it is possible to provide performance guarantees even if we select a “posterior” distribution over the hypothesis space after observing the labels of the training points \( X_m \). The guarantee is provided for a Gibbs algorithm, which is simply a stochastic classifier defined as follows. Let \( q \) be any distribution over \( H \). The corresponding Gibbs classifier, denoted by \( G_q \), classifies any new instance using a randomly chosen hypothesis \( h \in H \), with \( h \sim q \) (i.e. each new instance is classified with a potentially new random classifier).

For Gibbs classifiers we now extend definition (1) as follows. Let \( Z = x_1, \ldots, x_{|Z|} \) be any set of samples and let \( G_q \) be a Gibbs classifier over \( H \). The (expected) risk of \( G_q \) over \( Z \) is

\[
R_{G_q}(Z) \triangleq \mathbf{E}_{h \sim q} \left\{ \frac{1}{|Z|} \sum_{i=1}^{|Z|} \ell(h(x_i), \phi(x_i)) \right\}.
\]

As before, when \( Z = X_m \) (the training set) we use the standard notation \( \hat{R}_{G_q}(S_m) = R_{G_q}(X_m) \).

The first risk bound we state for transductive Gibbs classifiers is a simple extension of the recent inductive generalization bound for Gibbs classifiers presented in (McAllester, 2003b). The new transductive bound relies on reduction to independence and its proof follows almost exactly the proof of the original inductive result. We therefore omit the proof but note that the inductive bound relies on the variant of Theorem 11 (inequality (9)) for sampling with replacement. The new bound is obtained by bounding the divergence between the \( R_h(X_{m+u}) \) and \( \hat{R}_h(S_m) \) now relying on inequality (9), which concerns sampling without replacement. The bound on the transductive risk \( \hat{R}_h(X_u) \) is obtained using the following
simple generalization of Lemma 5. For all $q$ and $C$,
\[ R_{Gq}(X_{m+u}) \leq \hat{R}_{Gq}(S_m) + C \iff R_{Gq}(X_u) \leq \hat{R}_{Gq}(S_m) + \frac{m+u}{u} \cdot C, \]  
(12)

**Theorem 15 (Gibbs Classifiers)** Let $X_{m+u} = X_m \cup X_u$ be the full sample. Let $p = p(X_{m+u})$ be a (prior) distribution over $\mathcal{H}$ that may depend on the full sample. Let $\delta \in (0,1)$ be given. Then with probability at least $1 - \delta$ over the choices of $S_m$ (from the full sample) the following bound holds for any distribution $q$,
\[ R_{Gq}(X_u) \leq \hat{R}_{Gq}(S_m) + \left( \sqrt{\frac{2\hat{R}_{Gq}(S_m)(D(q\|p) + \ln \frac{m}{\delta})}{m-1}} + \frac{2(D(q\|p) + \ln \frac{m}{\delta})}{m-1} \right), \]
where $D(\cdot\|\cdot)$ is the familiar Kullback-Leibler (KL) divergence (see e.g. Cover and Thomas, 1991).

Notice that when $\hat{R}_{Gq}(S_m) = 0$ (the “realizable case”) fast convergence rates of order $1/m$ are possible when $u$ is sufficiently large (i.e. $u = \omega(m)$).

The next risk bound we present for transductive Gibbs binary classifiers relies on the “direct” concentration inequality of Theorem 13, for sampling without replacement. The proof is based on the proof technique recently presented in (McAllester, 2003b), which, in turn, is based on (Langford and Shawe-Taylor, 2002, Seeger, 2003).

**Theorem 16 (Binary Gibbs Classifiers)** Let the conditions of Theorem 15 hold, and assume the loss is binary. Then with probability at least $1 - \delta$ over the choices of $S_m$ (from the full sample) the following bound holds for any distribution $q$.
\[ R_{Gq}(X_u) \leq \hat{R}_{Gq}(S_m) + \sqrt{\frac{2\hat{R}_{Gq}(S_m)(D(q\|p) + \ln \frac{m}{\delta})}{m-1}} + \frac{2(D(q\|p) + \ln \frac{m}{\delta})}{m-1} + 7 \log(m+u+1) \]
\[ + \frac{2(D(q\|p) + \ln \frac{m}{\delta} + 7 \log(m+u+1))}{m-1}, \]
(13)

Before we prove Theorem 16 observe that when $\hat{R}_{Gq}(S_m) = 0$ (the “realizable case”) the bound converges even if $u = 1$. In contrast, the bound of Theorem 15 diverges in the realizable case for any $u = O(\sqrt{m})$.

For proving Theorem 16 we quote without proof two results from (McAllester, 2003b).

**Lemma 17** (McAllester (2003b), Lemma 5) Let $X$ be a random variable satisfying $\Pr\{X > x\} \leq e^{-mf(x)}$ where $f(x)$ is non-negative. Then $E\left[e^{(m-1)f(X)}\right] \leq m$.

**Lemma 18** (McAllester (2003b), Lemma 8) $E_{x \sim q}[f(x)] \leq D(q\|p) + \ln E_{x \sim p} e^{f(x)}$.

**Proof of Theorem 16:** The proof is based on the ideas in (McAllester, 2003b). Define $\hat{\nu}_h \triangleq \hat{R}_h(S_m)$; $\mu_h \triangleq R_h(X_{m+u})$. 

12
Let
\[ f_h(\nu) \triangleq D(\nu \| \mu_h) + \frac{u}{m} D \left( \frac{\mu_h - \beta \nu}{1 - \beta} \| \mu_h \right) - \frac{7}{m} \log (m + u + 1) \]

From Lemma 18 we have that
\[ \mathbb{E}_{h \sim q} [(m - 1) f_h(\nu)] \leq D(q \| p) + \ln \mathbb{E}_{h \sim p} [e^{(m-1)f_h(\nu)}] \tag{14} \]

An upper bound on \( \mathbb{E}_{h \sim p} [e^{(m-1)f_h(\nu)}] \) may be obtained by the following argument. From Theorem 13 we have that
\[ \text{Pr} \{ \hat{\nu}_h > \nu \} \leq \exp \{-mf_h(\hat{\nu}_h)\}. \]

Lemma 17 then implies that for any \( h \)
\[ \mathbb{E}_{\Sigma_m} [e^{(m-1)f_h(\hat{\nu}_h)]} \leq m, \]
which implies that
\[ \mathbb{E}_{\Sigma_m} \mathbb{E}_{h \sim p} [e^{(m-1)f_h(\hat{\nu}_h)]} \leq m, \]
from which we infer that with probability at least \( 1 - \delta \),
\[ \mathbb{E}_{h \sim p} [e^{(m-1)f_h(\hat{\nu}_h)]} \leq \frac{m}{\delta} \]

by using Markov’s inequality. Substituting in (14) we find that with probability at least \( 1 - \delta \)
\[ \mathbb{E}_{h \sim q} [(m - 1) f_h(\hat{\nu}_h)] \leq D(q \| p) + \frac{m}{\delta}. \tag{15} \]

Substituting for \( f_h(\hat{\nu}_h) \), and using the convexity of the function \( x \log x \), we find that
\[
D(\hat{R}_{G_q}(S_m) \| R_{G_q}(X_{m+u})) + \frac{u}{m} D \left( \frac{R_{G_q}(X_{m+u}) - \beta \hat{R}_{G_q}(S_m)}{1 - \beta} \| R_{G_q}(X_{m+u}) \right) - \frac{7}{m} \log (m + u + 1) \\
\leq \frac{D(q \| p) + \ln \frac{m}{\delta} + 7 \log (m + u + 1)}{m - 1}. \tag{16} 
\]

In order to obtain an explicit bound, we use the inequality
\[ D(\nu \| \mu) \geq \frac{(\nu - \mu)^2}{2\mu}, \]
and substitute this in (16) obtaining
\[
\frac{R_{G_q}(X_{m+u})}{z} \leq \hat{R}_{G_q}(S_m) + \frac{R_{G_q}(X_{m+u})}{z} \left( \frac{2u}{m + u} \right) \frac{D(q \| p) + \ln \frac{m}{\delta} + 7 \log (m + u + 1)}{m - 1}. \]

Thus we have (with probability at least \( 1 - \delta \)), \( z \leq a + b + \sqrt{ab} \) (where \( z = R_{G_q}(X_{m+u}) \)). Solving for \( z \) we get \( z \leq a + b + \sqrt{ab} \), and using Lemma 5 yields the desired result. \( \square \)
Remark 19 It is interesting to compare the bound of Theorem 15, based on the reduction to independence approach, and that of Theorem 16 which is based on a direct concentration inequality for sampling without replacement. The complexity term in Theorem 15 is multiplied by \((m + u)/u\), while the corresponding term in Theorem 16 is multiplied by \(\sqrt{(m + u)/u}\). This clearly displays the advantage of using the direct concentration bound, even though it does not lead to improved convergence rates in general. More importantly, for the realizable case, \(\hat{R}_{Gq}(S_m) = 0\), the bound of Theorem 16 converges to zero even for \(u = 1\). This is not the case for the bound of Theorem 15.

4.2 Bounds for Deterministic Learning Algorithms

In this section we present three transductive PAC-Bayesian error bounds for deterministic learning algorithms. Note that the two bounds we present for the (stochastic) Gibbs algorithms in the previous subsection can be specialized to deterministic algorithms. This is done by choosing a “posterior” \(q\) which assigns probability 1 to one desired hypothesis \(h \in \mathcal{H}\). In doing so the term \(D(q\|p)\) reduces to \(\log(1/p(h))\). For example, the bound of Theorem 15 reduces to

\[
R_h(X_u) \leq \hat{R}_h(S_m) + \left(\frac{m + u}{u}\right) \left(\sqrt{\frac{2\hat{R}_h(S_m) \left(\log \frac{1}{p(h)} + \ln \frac{m}{\delta}\right)}{m - 1}} + 2 \left(\log \frac{1}{p(h)} + \ln \frac{m}{\delta}\right)\right),
\]

which applies to any bounded loss function.

The following bound relies of the Serfling concentration inequality presented in Theorem 12 and applies to any bounded loss function.

**Theorem 20** Let \(X_{m+u} = X_m \cup X_u\) be the full sample and let \(p = p(X_{m+u})\) be a (prior) distribution over \(\mathcal{H}\) that may depend on the full sample. Assume that \(\ell(h(x), y) \in [0, B]\) and let \(\delta \in (0, 1)\) be given. Then, with probability at least \(1 - \delta\) over choices of \(S_m\) (from the full sample) the following bound holds for any \(h \in \mathcal{H}\),

\[
R_h(X_u) \leq \hat{R}_h(S_m) + B \sqrt{\left(\frac{m + u}{u}\right) \left(\frac{u + 1}{u}\right) \left(\frac{\ln \frac{1}{p(h)} + \frac{1}{2m}}{2}\right)}. \tag{18}
\]

**Proof:** In our transduction setting the set \(X_m\) (and therefore \(S_m\)) is obtained by sampling the full sample \(X_{m+u}\) uniformly at random without replacement. It is not hard to see that \(\mathbb{E}_{\Sigma_m} \hat{R}_h(S_m) = R_h(X_{m+u})\). Specifically,

\[
\mathbb{E}_{\Sigma_m} \hat{R}_h(S_m) = \frac{1}{\binom{m+u}{m}} \sum_{S_m} \hat{R}_h(S_m) = \frac{1}{\binom{m+u}{m}} \sum_{X_{m+u} \subseteq X_m} \frac{1}{m} \sum_{x \in S_m} \ell(h(x), \phi(x)). \tag{19}
\]

By symmetry, all points \(x \in X_{m+u}\) are counted on the right-hand side an equal number of times; this number is precisely \(\binom{m+u}{m} - \binom{m+u-1}{m-1} = \binom{m+u-1}{m-1}\). The result is obtained by

---

9. Although we have not utilized the Serfling inequality for devising a bound for the Gibbs algorithm, it can be done as well.
considering the definition of $R_h(X_{m+u})$ and noting that $\binom{m+u-1}{m-1}/\binom{m+u}{m} = \frac{m}{m+u}$. Using the fact that our loss function is bounded in $[0, B]$ we apply Theorem 12 (for a fixed $h$ and $N = m + u$),

$$\Pr_{\Sigma_m} \left\{ \mathbb{E}\hat{R}_h(S_m) - \hat{R}_h(S_m) > \varepsilon \right\} \leq e^{-\frac{2m\varepsilon^2}{B^2} \left( \frac{m+u}{u+1} \right)}.$$

(20)

Setting $\varepsilon(h) = B \sqrt{\frac{(u+1)(\ln \frac{1}{p(h)} + \ln \frac{1}{\delta})}{(m+u)2m}}$ and using the union bound we find

$$\Pr_{\Sigma_m} \left\{ \exists h \in H \text{ s.t. } R_h(X_{m+u}) - \hat{R}_h(S_m) > \varepsilon(h) \right\} \leq \sum_h \exp \left\{ -\frac{2m\varepsilon(h)^2}{B^2} \left( \frac{m + u}{u + 1} \right) \right\}
= \sum_h p(h) \delta
= \delta.$$

We thus obtain that

$$R_h(X_{m+u}) \leq \hat{R}_h(S_m) + B \sqrt{\frac{u + 1}{m + u} \left( \frac{\ln \frac{1}{p(h)} + \ln \frac{1}{\delta}}{2m} \right)}.$$

(21)

The proof is then completed using Lemma 5. $\square$

For classification using the 0/1 loss function we present one bound, which is a specialization of Theorem 16.

**Corollary 21** Let the conditions of Theorem 20 hold and assume the loss is binary. Then with probability at least $1 - \delta$ over the choices of $S_m$ (from the full sample) the following bound holds for any distribution $q$,

$$R_h(X_u) \leq \hat{R}_h(S_m) + \sqrt{\frac{2\hat{R}_h(S_m)(m + u)}{u} \log \frac{1}{p(h)} + \ln \frac{m}{\delta} + 7 \log(m + u + 1)}
+ 2 \left( \log \frac{1}{p(h)} + \ln \frac{m}{\delta} + 7 \log(m + u + 1) \right) \frac{\ln m + 7 \log(m + u + 1)}{m - 1}.$$

Figures 1 and 2 compare the two bounds presented in this section with Vapnik’s bound of Corollary 8. Throughout the discussion here the bound of Theorem 20 is referred to as the “Serfling bound”. Figure 1 focuses on the realizable case (i.e. empirical error = 0). According to the statements of Theorem 20 and Corollary 21, the Serfling bound has a significantly slower rate of convergence in the realizable case. However, the constants (and logarithmic terms) are larger in the bound of Corollary 21. Panels (a) and (b) in Figure 1 indicate that the Serfling bound is significantly better than the bound of Corollary 21 when $u = \Omega(m)$ for the range of $m$ we consider. However even in these cases, we know that the bound of Corollary 21 will eventually outperform the Serfling bound even in these cases. We also see that the Serfling bound tracks Vapnik’s bound quite well when $u = \Omega(m)$. On the other hand, Panels (c) and (d) indicate that the bound of Corollary 21 is significantly
better than the Serfling bound when \( u = o(m) \). The examples given are \( u = \sqrt{m} \) in Panel (c) and \( u = 10 \) in Panel (d). Figure 2 shows these bounds for the case \( \hat{R}_h(S_m) = 0.2 \). Here again the Serfling bound nicely tracks the Vapnik bound and we see that the bound of Corollary 21 converges much more slowly. All the curves in Figures 1 and 2 consider the case \( p(h) = 1 \). This assignment of the prior eliminates the influence of the union bound that is used to derive these bounds. In Figure 3 we show, for both the Vapnik and Serfling bounds, the complexity term as a function of the prior \( p(h) \), with \( 0.01 \leq p(h) \leq 1 \). Note that such prior assignments are realistic in the case of the transduction algorithm based on clustering that is introduced in Section 6.

4.3 On Priors and Prior Decompositions

PAC-Bayesian generalization (inductive) bounds or transductive risk bounds (as we present here) are interesting because they provide a very simple yet general formulation of learning. However, in order to provide more concrete statements (e.g. about specific learning algorithms) one must apply such bounds with some concrete priors (and posteriors, in the case of Gibbs learning, see Theorems 15 and 16). In the context of inductive learning, a major obstacle in deriving effective bounds\(^{10}\) using the PAC-Bayesian framework is the construction of “compact priors”. For example, the McAllester generalization bound in (McAllester, 1999a) contains a complexity term which includes a component of the form \( \ln(1/p(h)) \) where \( p \) is a prior over \( \mathcal{H} \) (as in Theorem 20 and Corollary 21). The more sophisticated bounds in (McAllester, 2003a,b) include a Kullback-Leibler (KL) divergence complexity component \( D(q||p) \) where \( p \) is a prior over \( \mathcal{H} \) and \( q \) is a posterior over \( \mathcal{H} \) (as in Theorems 15 and 16). However, many hypothesis classes of interest are very large and even uncountably infinite. Therefore, despite the fact that these bounds apply in principle to very large \( \mathcal{H} \), in a straightforward application of these PAC-Bayesian bounds, when choosing priors with a very large support (and possibly a posterior with a small support), the complexity terms in these bounds can diverge or at least be too large to form effective generalization bounds.\(^{11}\)

In contrast, the transductive setup provides a very convenient setting for applying PAC-Bayesian bounds. Here priors can be chosen after observing and analyzing the full sample. As already mentioned, even if we consider a very large hypothesis space \( \mathcal{H} \), after observing the full sample, the effective size of equivalence classes of hypotheses in \( \mathcal{H} \) is always finite and not larger than the number of dichotomies of the full sample. Moreover, as we later show one can form substantially more compact priors by analyzing the geometry of the full sample.

We now discuss a very simple technique that allows for the decompositions of priors into a collection of simpler priors. In subsequent sections we use this technique and easily derive new bounds for specific (transductive) learning algorithms. The (simple) observation is that instead of a single prior \( p \) in “standard” PAC-Bayesian bounds (for deterministic algorithms) one can use any PAC-Bayesian bound with a number of priors \( p_1, \ldots, p_k \) and then replace the complexity term \( \ln(1/p(h)) \) by \( \min_i \ln(1/p_i(h)) \), at a cost of an additional

\(^{10}\) Informally, we say that a bound is “effective” if its complexity term vanishes with \( m \) (the size of the training sample) and it is sufficiently small for “reasonable” values \( m \).

\(^{11}\) Saying that we should also note that sophisticated prior choices within the PAC-Bayesian framework can also lead to state-of-the-art bounds as presented in (McAllester, 2003b).
Explicit Error Bounds for Transductive Learning

Figure 1: A comparison of Vapnik's bound (Corollary 8), the bound of Theorem 20 (denoted here by “Serfling bound”) and the bound of Corollary 21. All bounds assume zero empirical error, $\delta = 0.01$ and $p(h) = 1$. (a) $u = 10m$; (b) $u = m$; (c) $u = \sqrt{m}$; and (d) $u = 10$.

In $k$ term (see below). Similarly, in PAC-Bayesian bounds for the Gibbs algorithm (e.g. Theorem 15) we can replace the KL-divergence term in the bound with $\min_i D(q||p_i)$. The penalty for using $k$ priors is logarithmic in $k$ (specifically the $\ln(1/\delta)$ term in the original bound becomes $\ln(k/\delta)$). Thus, one can decompose a complex prior into a very large number of components and as long as $k$ is sub-exponential in $m$ we still obtain useful generalization bounds. This can be formulated by a minor extension of the PAC-Bayesian bounds, which for simplicity is stated here as the following extension of Theorem 20. Similar extensions hold for all the PAC-Bayesian error bounds presented here and elsewhere.
Figure 2: A comparison of Vapnik’s bound (Corollary 8), the bound of Theorem 20 (denoted here by “Serfling bound”) and the bound of Corollary 21. All bounds assume empirical error of 0.2, $\delta = 0.01$ and $p(h) = 1$. (a) $u = 10m$; (b) $u = m$.

Figure 3: The complexity term of the Vapnik and Serfling bounds as a function of $p(h)$ with $0.01 \leq p(h) \leq 1$, $\delta = 0.01$ and $m = u = 50$.

**Theorem 22 (Multiple Priors)** Let the conditions of Theorem 20 hold, except that we now have $k$ prior distributions $p_1, \ldots, p_k$ defined over $\mathcal{H}$, each of which may depend on $X_{m+u}$. Let $\delta \in (0, 1)$ be given. Then, with probability at least $1 - \delta$ over random choices of
Explicit Error Bounds for Transductive Learning

sub-samples of size $m$ from the full-sample, for all $h \in \mathcal{H}$,

$$R_h(X_u) \leq \hat{R}_h(S_m) + \sqrt{\frac{m + u}{u}} \left( \frac{u + 1}{u} \right) \left( \min_{1 \leq i \leq k} \left\{ \ln \frac{1}{p_i(h)} + \ln \frac{k}{\delta} \right\} \right).$$

**Proof:** The proof uses a standard “multiple testing” argument. Consider $k$ applications of Theorem 20 such that each application is with $\delta' = \delta/k$ and the $i$th application uses $p_i$ as prior. The complexity term in the bound corresponding to the $i$th prior is

$$\sqrt{\frac{m + u}{u}} \left( \frac{u + 1}{u} \right) \left( \ln \frac{1}{p_i(h)} + \ln \frac{k}{\delta} \right).$$

Each of the $k$ bounds holds with probability at least $1 - \frac{\delta}{k}$ (and violated with probability at most $\frac{\delta}{k}$). Therefore, by the union bound the probability that at least one of these bounds is violated is at most $\delta$ and the probability that they all hold is at least $1 - \delta$ as required. □

**Remark 23** As noted by one of the reviewers, when the supports of the $k$ priors in Theorem 22 intersect (i.e. there is at least one pair of priors $p_i$ and $p_j$ with overlapping support), then one can do better by utilizing the “super prior” $p = \frac{1}{k} \sum_i p_i$ within the original Theorem 20. However, note that when the supports are disjoint, these two views (of multiple priors and a super prior) are equivalent.

5. Bounds for Compression Algorithms

Here we propose a technique for selecting (multiple) prior probabilities $p_i(h)$ based on the unlabeled sample $X_{m+u}$. This technique allows for tight error bounds for “compression” algorithms. Let $\mathcal{A}$ be a learning algorithm. Intuitively, $\mathcal{A}$ is a “compression scheme” if it can generate the same hypothesis using a subset of the (labeled) training data.

**Definition 24** A learning algorithm $\mathcal{A}$ (viewed as a function from samples to some hypothesis class) is a compression scheme with respect to a sample $Z$ if there is a sub-sample $Z'$, $|Z'| < |Z|$, such that $\mathcal{A}(Z') = \mathcal{A}(Z)$.

Observe that the SVM approach is a compression scheme, where the set $Z'$ is determined by the set of support vectors.

Let $\mathcal{A}$ be a deterministic compression scheme and consider the full sample $X_{m+u}$. For each integer $\tau = 1, \ldots, m$, consider all subsets of $X_{m+u}$ of size $\tau$, and for each subset construct all possible dichotomies of that subset (note that we are not proposing this approach as a useful algorithm, but rather as a means to derive bounds; in practice one need not construct all these dichotomies). A deterministic algorithm $\mathcal{A}$ generates at most one hypothesis $h \in \mathcal{H}$ for each dichotomy.\footnote{It might be that for some dichotomies the learning algorithm will fail to construct a classifier. For example, a linear SVM in feature space without “soft margin” will fail to classify non linearly-separable dichotomies of $X_{m+u}$.} For each $\tau$, let the set of hypotheses generated by this
procedure be denoted by $\mathcal{H}_\tau$. For the rest of this discussion we assume the worst case where $|\mathcal{H}_\tau| = 2^\tau \binom{m+u}{\tau}$ (i.e. if $\mathcal{H}_\tau$ does not contains one hypothesis for each dichotomy the bounds we propose below improve). The prior $p_\tau$ is then defined to be a uniform distribution over $\mathcal{H}_\tau$.

In this way we have $m$ priors, $p_1, \ldots, p_m$ which are constructed using only $X_{m+u}$ and are independent of the labels of the training set $Y_m$; also note that this construction takes place before choosing the subset $X_m$. Any hypothesis selected by the learning algorithm $A$ based on the labeled sample $S_m$ and on the test set $X_u$ belongs to $\bigcup_{\tau=1}^m \mathcal{H}_\tau$. The motivation for this construction is as follows. Each $\tau$ can be viewed as our “guess” for the maximal number of compression points that will be utilized by a resulting classifier. For each such $\tau$ the prior $p_\tau$ is constructed over all possible classifiers that use $\tau$ compression points. By systematically considering all possible dichotomies of $\tau$ points we can characterize a relatively small subset of $\mathcal{H}$ without observing labels of the training points. Thus, each prior $p_\tau$ represents one such guess. Using Theorem 22 we are later allowed to choose in retrospect the bound corresponding to the best “guess”.

The following corollary identifies an upper bound on the divergence in terms of the observed size of the compression set of the final classifier.

**Corollary 25 (Transductive Compression Bound)** Let the conditions of Theorem 22 hold. Let $A$ be a deterministic learning algorithm leading to a hypothesis $h \in \mathcal{H}$ based on a compression set of size $s$. Then with probability at least $1 - \delta$

$$R_h(X_u) \leq \hat{R}_h(S_m) + \sqrt{\left( \frac{m + u}{u} \right) \left( \frac{u + 1}{u} \right) \left( s \ln \left( \frac{2e(m+u)}{s} \right) + \ln(m/\delta) \right)}.$$  \hfill (22)

**Proof:** Recall that $\mathcal{H}_s \subseteq \mathcal{H}$ is the support set of $p_s$ and that $p_s(h) = 1/|\mathcal{H}_s|$ for all $h \in \mathcal{H}_s$, implying that $\ln(1/p_s(h)) = |\mathcal{H}_s|$. Using the inequality $\binom{m+u}{s} \leq (e(m+u)/s)^s$ we have that $|\mathcal{H}_s| = 2^s \binom{m+u}{s} \leq (2e(m+u)/s)^s$. Substituting this expression of $\ln(1/p_s(h))$ in Theorem 22 leads to the desired result. \hfill \Box

**Remark 26** Note that in the case of binary classifiers we can use Corollary 21 to get a similar result, which is sometimes tighter. Also, such compression bounds can be easily stated and proved for Gibbs learning.

The bound (22) can be easily computed once the classifier is trained. If the size of the compression set happens to be small, we obtain a tight bound. We note that these bounds are applicable to the transductive SVM algorithms discussed in (Vapnik, 1998, Bennett and Demiriz, 1998, Joachims, 1999). However, our bounds motivate a different strategy than the one that drives these algorithms; namely, reduce the number of support vectors! (rather than enlarge the margin, as attempted by those algorithms).

Note the conceptual similarity of our bound to Vapnik’s bound for consistent SVMs (Vapnik, 1995, Theorem 5.2), which bounds the generalization error of an SVM by the ratio between the average number of support vectors and the sample size $m$. However, Vapnik’s bound can be only estimated while this bound is truly data dependent. Finally, it is interesting to compare our result to a recent inductive bound for compression schemes.
In this context Graepel et al. (see Theorem 5.18 in Herbrich, 2002) have derived a bound of the form
\[
R(\text{SVM}) \leq \frac{m}{m-s} \hat{R}(\text{SVM}) + \sqrt{\frac{s \log(2em/s) + \ln(1/\delta) + 2 \ln m}{2(m-s)}},
\]
(23)
where \( R(\text{SVM}) \) and \( \hat{R}(\text{SVM}) \) denote the true and empirical errors, respectively, and \( s \) is the number of observed support vectors (over the training set).

6. Transductive Learning via Clustering

Some learning problems do not allow for high compression rates using compression schemes such as SVMs (i.e. the number of support vectors can sometimes be very large, see e.g. Baram et al., 2003). A considerably stronger type of compression can often be achieved by clustering algorithms. While there is lack of formal links between entirely unsupervised clustering and classification, within a transductive setting we can provide a principled approach to using clustering algorithms for classification. Let \( \mathcal{A} \) be any (deterministic) clustering algorithm which, given the full sample \( X_{m+u} \), can cluster this sample into any desired number of clusters. We use \( \mathcal{A} \) to cluster \( X_{m+u} \) into \( 1, \ldots, c \) clusters where \( c \leq m \). Thus, the algorithm generates a collection of partitions of \( X_{m+u} \) into \( \tau = 1, 2, \ldots, c \) clusters, where each partition is denoted by \( C_\tau \). For each value of \( \tau \), let \( \mathcal{H}_\tau \) consist of those hypotheses which assign an identical label to all points in the same cluster of partition \( C_\tau \), and define the prior \( p_\tau(h) = 1/2^\tau \) for each \( h \in \mathcal{H}_\tau \) and zero otherwise (note that there are \( 2^\tau \) possible dichotomies). The learning algorithm selects a hypothesis as follows. Upon observing the labeled sample \( S_m = (X_m, Y_m) \), for each of the clusterings \( C_1, \ldots, C_c \) constructed above, it assigns a label to each cluster based on the majority vote from the labels \( Y_m \) of points falling within the cluster (in case of ties, or if no points from \( X_m \) belong to the cluster, choose a label arbitrarily). Doing this leads to \( c \) classifiers \( h_\tau \), \( \tau = 1, \ldots, c \). For each \( h_\tau \) there is a valid error bound as given by Theorem 22 and all these bounds are valid simultaneously. Thus we choose the best classifier (equivalently, number of clusters) for which the best bound holds. We thus have the following corollary of Theorem 22.

**Corollary 27** Let \( \mathcal{A} \) be any clustering algorithm and let \( h_\tau \), \( \tau = 1, \ldots, c \) be classifications of the test set \( X_u \) as determined by clustering of the full sample \( X_{m+u} \) (into \( \tau \) clusters) and the training set \( S_m \), as described above. Let \( \delta \in (0,1) \) be given. Then, with probability at least \( 1 - \delta \) over choices of \( S_m \) the following bound holds for all \( \tau \),
\[
R_{h_\tau}(X_u) \leq \hat{R}_{h_\tau}(S_m) + \sqrt{(\frac{m+u}{u}) (\frac{u+1}{u}) (\frac{\tau + \ln \frac{\tau}{\delta}}{2m})}
\]
(24)

**Remark:** Note that when \( m = u \) we get the bound
\[
R_{h_\tau}(X_u) \leq \hat{R}_{h_\tau}(S_m) + \sqrt{(\frac{1}{m}) (\frac{\tau + \ln \frac{\tau}{\delta}}{m})}
\]
Also, in the case of the 0/1 loss we can use Corollary 21 to obtain significantly faster rates in the realizable case or when the training error is very small. We see that these bounds can
be rather tight when the clustering algorithm is successful (e.g. when it captures the class structure in the data using a small number of clusters). Note however, that in practice one can significantly benefit by the faster rates that can be achieved utilizing Vapnik’s implicit bound in Corollary 8.

Corollary 27 can be extended in a number of ways. One simple extension is the use of an ensemble of clustering algorithms. Specifically, we can concurrently apply $k$ clustering algorithm (using each algorithm to cluster the data into $\tau = 1, \ldots, c$ clusters). We thus obtain $kc$ hypotheses (partitions of $X_{m+u}$). By a simple application of the union bound we can replace $\ln \frac{c}{\delta}$ by $\ln \frac{kc}{\delta}$ in Corollary 27 and guarantee that $kc$ bounds hold simultaneously for all $kc$ hypotheses (with probability at least $1 - \delta$). We thus choose the hypothesis which minimizes the resulting bound. This extension is particularly attractive since typically without prior knowledge we do not know which clustering algorithm will be effective for the dataset at hand.

7. Concluding Remarks

We presented general bounds for transductive learning. We also developed a new technique for deriving tight error bounds for compression schemes and for clustering algorithms in the transductive setting. While we presented some of our results within the simplest binary classification setting (i.e. with the zero-one loss function and with non-stochastic labels), they can be extended to many other learning settings including multi-class problems, stochastic labels, and any bounded loss function. We expect that these bounds and techniques will be useful for deriving error bounds for other known algorithms and for deriving new types of transductive learning algorithms.

While in the case of classification (i.e. the 0/1 loss) implicit (and tighter!) error bounds for transduction were already known (i.e. Vapnik’s result as formulated in Corollary 8) our bounds are explicit. It is clear that the implicit bounds are tighter and should be used in practical applications. However, the explicit bounds are important for understanding the nature of learning as characterized by the functional dependency on the problem parameters. In the case of general bounded loss functions (e.g. regression) our error bounds may be the first general result for transduction. Also, we present the first general bounds for the transductive Gibbs algorithm.

An interesting feature of our (and other) transduction error bounds (within Setting 1) is that they hold for “individual samples”; that is, the full sample $X_{m+u}$ need not be sampled i.i.d. from a distribution and moreover, we do not have to assume that it is sampled from a fixed distribution at all! The results simply hold for any given sample. In this sense, the transductive bounds are considerably more robust than standard bounds in the inductive setting.

An interesting direction for future research is the construction of more sophisticated (multiple) priors. For example, in our compression bound (Corollary 25), for each number $s$ of compression points we assigned the same prior to each dichotomy of each $s$-subset. However, in practice, when there is structure in the data, the vast majority of all these subsets and dichotomies cannot “explain” the data and should not be assigned a large prior.
All our results are obtained within Vapnik’s “Setting 1” of transduction, which must consider any arbitrary choice of the full sample. Considering Theorem 2 and Remark 4 it is interesting to see if tighter results are possible within the probabilistic Setting 2.

Finally, we note that the major challenge, of determining a precise relation between the inductive and transductive learning schemes remains open. Our bounds suggest that transduction does not allow for learning rates that are faster than induction (as a function of $m$). However, as far as we know the bound we obtain for clustering algorithms is perhaps the tightest known for a specific learning algorithm.

Appendix A. Proof of Theorem 2

Proof: The proof we present is identical to Vapnik’s original proof and is provided for the sake of self-completeness. Let $\mathcal{A}$ be some learning algorithm choosing an hypothesis $h_\mathcal{A} \in \mathcal{H}$ based on $S_m \cup X_u$. Define

$$C_\mathcal{A}(x_1, y_1; \ldots ; x_{m+u}, y_{m+u}) = \left| \frac{1}{m} \sum_{i=1}^{m} \ell(y_i, h_\mathcal{A}(x_i)) - \frac{1}{m+u} \sum_{j=m+1}^{m+u} \ell(y_i, h_\mathcal{A}(x_i)) \right| = |R_{h_\mathcal{A}}(X_m) - R_{h_\mathcal{A}}(X_u)|.$$ 

Consider Setting 2. The probability that $C_\mathcal{A}$ deviates from zero by an amount greater than $\varepsilon$ is

$$P = \int_{X,Y} \mathbb{I}(C_\mathcal{A} - \varepsilon) d\mu(x_1, y_1) \cdots d\mu(x_{m+u}, y_{m+u}),$$

where $\mathbb{I}$ is an indicator step function, $\mathbb{I}(x) = 1$ iff $x > 0$ and $\mathbb{I}(x) = 0$ otherwise. Let $T_p$, $p = 1, \ldots , (m+u)!$ be the permutation operator for the sample $(x_1, y_1; \ldots ; x_{m+u}, y_{m+u})$. It is not hard to see that

$$P = \int_{X,Y} \left\{ \frac{1}{(m+u)!} \sum_{p=1}^{(m+u)!} \mathbb{I}(C_\mathcal{A}(T_p(x_1, y_1; \ldots ; x_{m+u}, y_{m+u})) - \varepsilon) \right\} d\mu(x_1, y_1) \cdots d\mu(x_{m+u}, y_{m+u}).$$

The expression in curly braces is the quantity estimated in Setting 1 and by our assumption, for any choice of the full sample, it does not exceed $\delta$. Therefore,

$$P \leq \int_{X,Y} \delta d\mu(x_1, y_1) \cdots d\mu(x_{m+u}, y_{m+u}) = \delta.$$
