## ABSTRACT

Two tasks of communication in a multi-hop synchronous radio network are considered: point-to-point communication and broadcast (sending a message to all nodes of a network). Efficient protocols for both problems are presented. Even though the protocols are probabilistic, it is shown how to acknowledge messages deterministically.

Let  $n$ ,  $D$ , and  $\Delta$  be the number of nodes, the diameter and the maximum degree of our network, respectively. Both protocols require a setup phase in which a BFS tree is constructed. This phase takes  $O((n + D \log n) \log \Delta)$  time.

After the setup,  $k$  point-to-point transmissions require  $O((k + D) \log \Delta)$  time on the average. Therefore the network allows a new transmission every  $O(\log \Delta)$  time slots. Also,  $k$  broadcasts require an average of  $O((k + D) \log \Delta \log n)$  time. Hence the average throughput of the network is a broadcast every  $O(\log \Delta \log n)$  time slots. Both protocols pipeline the messages along the BFS tree. They are always successful on the graph spanned by the BFS tree. Their probabilistic behavior refers only to the running time.

Using the above protocols the ranking problem is solved in  $O(n \log n \log \Delta)$  time. The performance analysis of both protocols constitutes a new application of queueing theory.

**Keywords:** Radio networks, broadcast, point-to-point routing, distributed algorithms, average case analysis, Queueing Theory.

## 1. INTRODUCTION

A *radio network* is a network of processors which communicate using radio. The main characteristic of radio communication is that if a receiver is in the range of two or more transmitting stations then it does not receive anything. A radio communication network is *single-hop* if all nodes are in transmission range of each other. Otherwise it is *multi-hop*. Thus, sending a message between two stations in a multi-hop network might involve transmissions of intermediate stations.

Permission to copy without fee all or part of this material is granted provided that the copies are not made or distributed for direct commercial advantage, the ACM copyright notice and the title of the publication and its date appear, and notice is given that copying is by permission of the Association for Computing Machinery. To copy otherwise, or to republish, requires a fee and/or specific permission.

Real life radio networks for data communication are quite limited. In fact, most such networks are single-hop. The only existing multi-hop networks resort to the tree topology. This situation looks rather odd considering the ease in which radio networks can be initiated and the flexibility and modularity of their operation.

A new approach for controlling the activity in multi-hop radio networks was presented in the work of [BG187], where an efficient broadcast protocol is presented. Their method gives a new way of looking at radio networks. However, they do not provide protocols for many important network tasks.

In the present work we use some of the ideas presented in [BGI87], together with some new ideas to get very efficient protocols for two important and practical tasks. The tasks are  $k$  point-to-point transmission and  $k$ -broadcast. *Point-to-point transmission* is the task of sending a message from one station to another. *Broadcast* is a task initiated by a single stations called the *source*, which transmits a *message* to all stations in the network. A  $k$ -point-to-point transmission ( $k$ -broadcast) is a task which consists of  $k$  point-to-point transmissions ( $k$ -broadcasts). Besides the theoretical interest, these tasks constitute a major part of real-life multi-hop radio network.

**1.1 Model Description** Our model consists of an undirected graph whose nodes represent stations (i.e., processors) and whose edges indicate possible communication, (i.e., an edge between two nodes implies that the corresponding processors are within range of each other). The processor have distinct IDs. Initially, each processor knows its local neighborhood (i.e. the identity of its neighbors) the size of the network,  $n$ , and an upper bound  $\Delta$  on the maximum degree of the network. It need not have any additional information of the topology of the network.

The processors may transmit and receive messages of length  $O(\log n)$  and communicate in synchronous time-slots subject to the following rules. In each time-slot, each processor acts either as a *transmitter* or as a *receiver*. A processor acting as a receiver is said to receive a message in time-slot  $t$  if exactly one of its neighbors transmits in time-slot  $t$ . The message received is the one sent. Since communication is synchronous the only difficulty in routing messages, in this model, is the possibility of *conflicts*; that is, situations when several neighbors of a processor transmit simultaneously and it receives nothing. More specifically, we assume that there is no conflict detection, (see [BGI88]).

Throughout the paper,  $n$  denotes the actual number of processors,  $\Delta$  the maximum degree and  $D$  the diameter of the network.

**1.2 Main Results** Efficient protocols for  $k$ -point-to-point communication and  $k$ -broadcast are presented. Even though the protocols are probabilistic, it is shown how to acknowledge messages deterministically. Both protocols require a setup phase in which a BFS tree is constructed. This phase takes  $O((n + D \log n) \log \Delta)$  time.

After the setup,  $k$  point-to-point transmissions require  $O((k+D) \log \Delta)$  time on the average. Therefore the network allows a new transmission every  $O(\log \Delta)$  time

slots.

Also,  $k$  broadcasts require an average of  $O((k+D) \log \Delta \log n)$  time. Hence the average throughput of the network is a broadcast every  $O(\log \Delta \log n)$  time slots.

Both protocols pipeline the messages along the edges of a BFS tree. They are always successful on the graph spanned by this tree. Their probabilistic behavior refers only to the running time. The performance analysis of both protocols constitutes a new application of queuing theory.

The main contributions of the current work is in the use of the BFS tree to pipeline the messages in the network, the acknowledgement mechanism and the usage of Queuing Theory for the analysis of the collection protocol. We feel that the last two contributions can be used in other applications.

**1.3 Previous Work** Chlamtac and Kutten [CK85] showed that, given a network and a designated source, finding an optimal broadcast schedule (i.e., broadcasting schedule which uses the minimum number of time-slots) is NP-Hard. They also routed messages through a (not necessarily BFS) tree, and discussed "implicit acknowledgements". Their acknowledgments are conducted in the absence of conflicts, which is achieved at the cost of increasing the time of a single point-to-point communication to  $O(D\Delta^2)$ .

Chlamtac and Weinstein [CW87] presented a polynomial-time (centralized) algorithm for constructing a broadcast schedule which uses  $O(D \log^2 n)$  time-slots. This centralized algorithm can be implemented in a distributed system assuming the availability of special control channels, but the number of control messages sent may be quadratic in the number of nodes of the network [We87].

Bar-Yehuda et al. [BGI87] described a randomized single-source broadcast protocol. To ensure that with probability  $1-\epsilon$  all nodes receive the message the protocol requires an average of  $O((D + \log \frac{n}{\epsilon}) \log \Delta)$  time slots. For  $D=2$ , they have also shown an  $\Omega(n)$  lower bound for deterministic protocols. Thus, for this problem there exist randomized protocols that are much more efficient than any deterministic one. For  $D=2$ , Alon et al. [ABLP88] showed an  $\Omega(\log^2 n)$  lower bound, which matches the upper bound of [BGI87].

In [BGI88] Bar-Yehuda et al. discuss several models

of radio communication and show how to detect conflicts and simulate a single hop network. Thus they show how to use protocols designed for the ETHERNET in a multi-hop network [C79, Ga85].

**1.4 Protocol Outline** Both protocols depend on the existence of a BFS tree of the graph which is constructed in a setup phase. During the setup part, a leader is chosen. Once the leader is chosen, it initiates the construction of a BFS tree whose root is the leader. For this purpose the protocols of [BG187] and [BG188] are used. The setup phase is conducted only once, after which any series of point-to-point transmissions or broadcasts might be performed.

The broadcast process is reactive (continuous), it is invoked whenever a source originates a message to broadcast. It consists of two subprotocols: *collection* – sending the messages from the sources to the root of the BFS tree and *distribution* – sending the messages from the root to all the processors of the network.

The point-to-point transmission is also reactive. It is invoked whenever a processor wishes to send a message. A message from node  $u$  to  $v$  travels first up the tree. Once the message reaches a common ancestor of  $u$  and  $v$  it continues downwards towards  $v$ . The protocols for both directions are very similar to the collection protocol and are fully described in section 5.

Since both protocols are reactive, it is not possible to wait until all the messages have finished to travel upwards, and only then start their journey downwards. Therefore, in both protocols the collection and distribution subprotocols are conducted concurrently, either by using separate channels or by multiplexing: odd time slots are dedicated to the upward traffic (collection) and the even ones to the downwards traffic. We shall not elaborate further and assume separate channels.

All our protocols make use of a basic protocol, *Decay* [BG187] for passing messages from one layer to the next. In the sequel we use the term *send* whenever *Decay* is used.

```

procedure Decay ( $m$ );
repeat at most  $2\log\Delta$  times
    transmit  $m$  to all neighbors;
    flip  $coin \in_R \{0,1\}$ 
until  $coin = 0$ .

```

*Decay* is a probabilistic protocol, with the following

properties:

- (1) It lasts  $2\log\Delta$  time slots.
- (2) If several neighbors of a node  $v$  use *Decay* to send messages then with probability greater than  $\frac{1}{2}$  the node  $v$  receives one of the messages.

Several of our protocols require that all successfully sent messages be acknowledged. We show that though there is positive probability that a message is not received, every message that has actually been received is acknowledged with certainty. The overhead of the acknowledgement mechanism is minimal – it slows down the protocol by a factor of 2. As a result the point to point transmission is always successful on the graph spanned by the BFS tree.

**1.5 Organization** Section 2 describes the setup phase. Since it relies on previous work we only show how to modify it for our needs. All the other results are entirely new. Section 3 describes the acknowledgement mechanism, Section 4 the collection protocol and its analysis, Section 5 the point-to-point transmission protocol and Section 6 the distribution protocol. An application, ranking, is described in Section 7. Concluding remarks appear in Section 8. The appendix contains a formal justification for the use of the queueing model.

## 2. THE SETUP PHASE

Our protocols require the existence of a basic communication subnetwork. This network consists of a leader which is a root of a BFS tree. Bar-Yehuda et al. [BG188] described how to find a leader in  $O((\log\log n) \cdot (D + \log \frac{n}{\epsilon}) \log\Delta)$  time.

In [BG187] Bar-Yehuda et al. describe how to find a BFS tree. Their algorithm requires  $O(D \log\Delta \log \frac{n}{\epsilon})$  time slots and succeeds with probability  $1-\epsilon$ . Since we have assumed that all the IDs are distinct and  $n$  is known to all the nodes, the leader election and BFS can be modified so that they always succeed, only the running time is probabilistic:

First, choose  $\epsilon = 1/n$ , thus with probability  $\geq 1-n^{-1}$  the leader election and the BFS protocol succeed. To make sure that the protocol always succeeds, when joining the tree each node sends a message to the root using the collection protocol of Section 4 below. This protocol only uses already constructed edges of the BFS tree, always

succeeds and requires an average of  $O(n \log \Delta)$  time slots to send all these messages. If the root does not receive all the messages by twice the expected time, it reinvokes the setup phase. Since the probability of reinvocation is less than  $\frac{1}{2}$ , the entire modified setup protocol lasts  $O(D \log \Delta \log n)$  time slots on the average.

**2.1. Preventing collisions from different levels.** An advantage of the BFS tree is that a collision at a node  $v$  at level  $i$  can occur only by messages sent from levels  $i-1$ ,  $i$  and  $i+1$ . Collisions of messages sent from different levels are prevented by using time multiplexing: We require that a node at level  $i$  transmits a message at time slot  $t$  only if  $t \equiv i \pmod 3$ . This increases the duration of our protocols by a factor of 3. Henceforth, we assume that this mechanism has been built into all our protocols.

### 3. THE ACKNOWLEDGEMENT PROTOCOL.

The protocols of sections 4 and 5 use messages which are each destined to a single processor. These protocols require that every message be acknowledged. We now show how to conduct acknowledgements deterministically. The odd time slots are dedicated to the original protocol and the even ones to acknowledgements. Namely, every node that receives a message sends an acknowledgement on the next time slot.

The next theorem shows the correctness of this protocol. The theorem depends on the fact that each message has a unique destination and that the destinations of different messages successfully received at the same time slot are distinct.

**Theorem 3.1:** *Let  $v$  be a node that received a message from node  $u$  using the above protocol, then  $u$  receives an acknowledgement.*

**Proof:** Suppose that  $v$  received the message from  $u$  at time slot  $t$  and that  $u$  did not receive the acknowledgement. According to the protocol,  $v$  sent an acknowledgement at time slot  $t+1$ . Since  $u$  did not receive the acknowledgement there must have been a conflict at  $u$ . I.e., at time slot  $t+1$  another node,  $v'$ , connected to  $u$  also sent an acknowledgement (see Figure 1). According to the protocol,  $v'$  would not send an acknowledgement unless it received a message destined to it at time slot  $t$ .

However, since the message sent by  $u$  was destined to  $v \neq v'$  and  $v'$  acknowledges only messages destined to it,  $v'$  received its message from a node  $u' \neq u$ . Therefore, at time slot  $t$  both  $u$  and  $u'$  sent messages, and since  $v'$  is connected to both of them, a conflict occurred at  $v'$  (at time

Figure 1

slot  $t$ ) and  $v'$  did not successfully receive any message. This contradicts the assumption that  $v'$  successfully received a message at time slot  $t$ .  $\square$

### 4. COLLECTION

The purpose of the collection protocol is to send messages from the sources to the root of the BFS tree. Since no source knows the number and IDs of the other sources this is done concurrently and independently by all of them.

Messages are sent, using *Decay*, via the BFS tree from BFS-children to their parents. To each message we append the ID of the node  $v$  which sent the message and the ID of  $v$ 's BFS-parent. This information enables a node to figure out whether the message was sent by its BFS-child, by its BFS-parent or by another node. The nodes will make use of this information and we shall omit the details of this.

**4.1. The collection protocol** Every node has a buffer of unacknowledged messages. Initially, all buffers except those of the sources are empty. The protocol proceeds in phases. In the odd time slots of each phase every node whose buffer is not empty executes *Decay* to send a message from its buffer to its BFS-parent. The even time slots are dedicated to acknowledgements as explained in Section 3. Every such message is resent until an acknowledgement is received. Whereupon, it is removed from the sender's buffer. When a message is received it is put on its receiver's buffer. Since the acknowledgement occurs immediately after sending, messages exist on exactly one buffer and proceed from child to parent.

**4.2. Analysis of the collection protocol** We first estimate how fast messages move from level to level.

**Theorem 4.1** *Let  $i \geq 1$  be a level containing messages at the beginning of a phase. There is probability  $\geq \gamma = e^{-1}(1-e^{-1}) \stackrel{\text{def}}{\approx} 0.2325$  that during the phase a message from level  $i$  is successfully received by its BFS parent.*

**Proof sketch:** A phase consists of a single invocation of *Decay*. At any given time, the nodes which still want to

transmit are called *live*. At each time slot each live processor first transmits and then with probability  $\frac{1}{2}$  dies. Therefore, on the average, half of the live nodes die at each time slot.

Let  $TRY_i$  be the set of nodes of level  $i$  who are live at time  $t=0$ . Consider two cases:

*Case 1,  $|TRY_i| \leq \Delta$ :* The analysis of *Decay* [BG187] implies that with probability  $\geq \frac{1}{2}$  there exists a time slot with exactly one live processor  $u$  of  $TRY_i$ . Hence, the BFS parent of  $u$  receives  $u$ 's message.

*Case 2,  $|TRY_i| > \Delta$ :* The probability that a node  $v \in TRY_i$  is live at time  $t_0 \stackrel{\text{def}}{=} \log \Delta$  is  $1/\Delta$ . The probability that  $TRY_i$  contains a live node at time  $t_0$  is  $1 - (1 - \frac{1}{\Delta})^{|TRY_i|} \geq 1 - (1 - \frac{1}{\Delta})^\Delta \geq 1 - e^{-1}$ .

Let  $u$  be such a node,  $w$  be its BFS-parent and  $S = \{v \in TRY_i \mid (v,w) \in E\} \setminus \{u\}$  (the transmitting neighbors of  $w$  not including  $u$ ). If at time  $t_0$ ,  $S$  contains no live nodes, then  $w$  receives  $u$ 's message. The existence of a live node in  $S$  is independent of the behavior of  $u$ . The probability that at time  $t_0$   $S$  contains no live node is

$$(1 - \frac{1}{\Delta})^{|S|} \geq \left(1 - \frac{1}{\Delta}\right)^{|\Delta-1|}$$

Since  $|S| \leq \Delta-1$  the above probability is  $\geq e^{-1}$ . Therefore, the probability of a successful transmission is  $\geq \text{Prob}(TRY_i \text{ contains a live node at time } t_0) \times$

$$\text{Prob}(\text{at time } t_0 \text{ all nodes in } S \text{ dead}) \geq (1 - e^{-1}) \times e^{-1}.$$

□

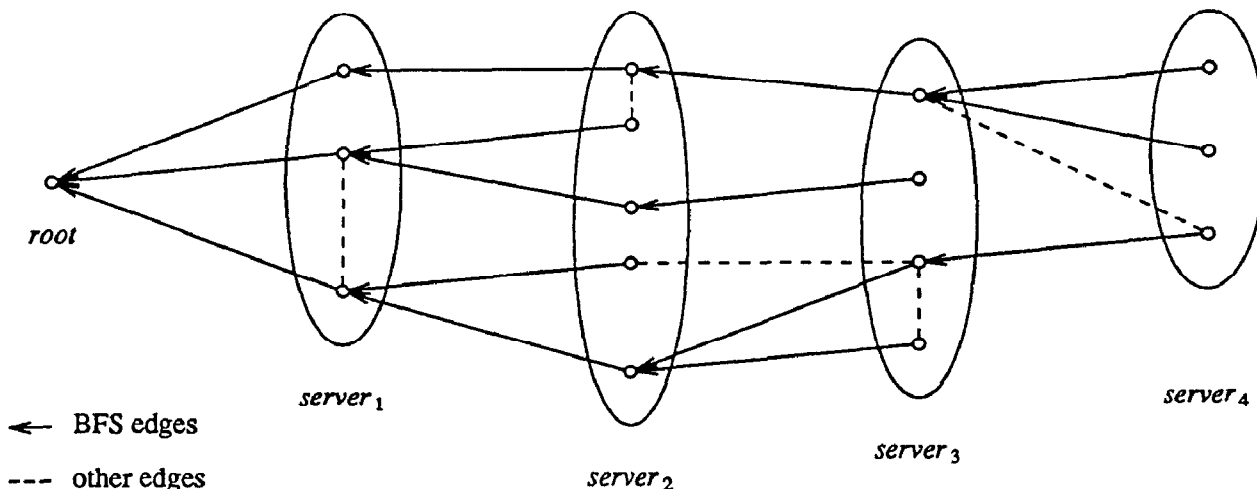

Figure 2 - The Queueing Model

We now use Queueing Theory to analyze the performance of the collection protocol. To that end, we model each level of the graph (except the root) as a server (see Figure 2). Thus we have  $D$  servers connected in series, with the output of the  $i$ th server being the input the  $i-1$ st. Theorem 4.1 shows that if there are customers (messages) at server (level)  $i$ , at some phase then with probability  $\geq \gamma$  a customer is served and moved to server  $i-1$  during that phase.

In our application at time  $t=0$  the messages are distributed over all levels. The processing time of our system is less than that of a system in which all messages originate at level  $D$  and instead of being already in the system at time  $t=0$ , their arrival process is Bernoulli with parameter  $\lambda$ . A formal treatment of these arguments appears in the appendix. We first analyze server  $D$ . It is a discrete  $M/M/1$  queue [K75] with parameters  $\lambda$  and  $\mu$ : Its birth process (arrival of customers) is Bernoulli with probability  $\lambda$ , while the death process (serving customers) is Bernoulli with probability  $\mu$ . Following Burke [B56], Hsu and Burke [HB76] analyzed the problem when  $\lambda < \mu$ .

**Theorem 4.2:** [HB76] Consider the departure process of the above queue (with  $\lambda < \mu$ ), i.e., let  $\delta(t) = 1$  if at time  $t$  a customer was processed, and  $\delta(t) = 0$  otherwise. Then  $\delta$  converges to a Bernoulli process with parameter  $\lambda$ .

They also showed that  $P_j(t)$  = the probability that at time  $t$  the length of the queue is  $j$  approaches a limit  $p_j$  and

$$p_0 = 1 - \frac{\lambda}{\mu}, \quad p_1 = \frac{\lambda}{(1 - \lambda)\mu} p_0,$$

$$p_j = \left[ \frac{\lambda(1-\mu)}{\mu(1-\lambda)} \right]^{j-1} p_1.$$

Thus the expected queue length is  $\bar{N} = \sum_{j \geq 0} j p_j = \frac{\lambda(1-\lambda)}{\mu-\lambda}$ .

By Little's result [K75 p. 17], the average time in the queue is,  $\bar{T} = \frac{\bar{N}}{\lambda} = \frac{1-\lambda}{\mu-\lambda}$ .

The major observation is that since the output of the  $i$ th server is the input to the  $i-1$ st, the input to all servers is Bernoulli with parameter  $\lambda$ . Using this observation we get,

**Theorem 4.3:** *The expected number of phases required for  $k$  messages to reach the root is at most  $2(1 + \sqrt{1-\gamma})\gamma^{-1}(k + D)$ .*

**Proof:** Theorem 4.2 holds asymptotically. Here we have only a finite number of messages. However the asymptotic results can be used (i.e.,  $t \rightarrow \infty$ ) since the queue sizes and the completion time are nondecreasing functions of  $t$ . Hence the limiting case is an upper bound.

The expected time for the  $k$ th message to arrive equals the expected time until it enters the queueing model  $= k/\lambda$ , plus the time to pass through the  $D$  servers  $= \frac{1-\lambda}{\mu-\lambda}D$ , i.e., a total of  $\frac{k}{\lambda} + \frac{1-\lambda}{\mu-\lambda}D$ .

Substituting  $\lambda = 1 - \sqrt{1-\gamma}$  and  $\mu = \gamma$  satisfies  $\lambda < \mu$  and yields the desired result.  $\square$

Since each phase lasts twice the time of *Decay* and  $\gamma = e^{-1}(1-e^{-1})$ , we get

**Corollary:** *The expected number of time slots for  $k$  messages to reach the root is bounded by  $32.27(k+D)\log\Delta$ .*

This constant can be improved using the techniques of [Ho87].

## 5. Point to Point Transmission

As mentioned before, this protocol consists of two subprotocols: the upward direction subprotocol from the initiator of the message  $u$  to a common ancestor  $w$  of  $u$  and the destination  $v$  and the downward direction subprotocol from  $w$  to  $v$ .

**5.1. The upward subprotocol** This protocol is essentially identical to the collection protocol, except that messages do not go all the way to the root but only to the least common ancestor of the originator and the destination which are included in the message. When the message reaches a BFS tree ancestor of the destination, the downward

protocol is invoked. To this end, each node should hold list of its BFS descendants.

The descendant information can be found once, right after the BFS tree is constructed: As soon as a node joins the BFS tree, it sends its ID to the root via all its ancestors. During the BFS protocol, each node can record its parent, thus to send a message to the root, it is sufficient to send it to that parent and ask it to send the message further. Whenever a node receives such a message from one of its children, it adds the ID of the originator of the message to the list of IDs of descendants. Conveying all the descendant information requires the collection of  $n-1$  messages, i.e.,  $O((n-1+D)\log\Delta) = O(n\log n)$  time.

**5.2. The downward subprotocol** This protocol is also very similar to the collection protocol. The messages are prepended with the ID of their final destination. Every node sends messages destined to its BFS children and keeps a buffer of unacknowledged downgoing messages. Here we also use *Decay*. On each phase a message is sent, according to that protocol. Messages are resent until an acknowledgement is received. A node  $w$  receiving a message destined to  $u$  processes it only if  $u$  is a BFS-tree descendant of  $w$ . To process a message,  $w$  acknowledges it and if  $w \neq u$  it is put on  $w$ 's downgoing buffer.

**5.3. Performance analysis** The setup phase requires  $O(n\log\Delta)$  time after which passing  $k$  messages requires an average of  $O((k+D)\log\Delta)$  time. When  $k \rightarrow \infty$  the average time per message is  $O(\log\Delta)$ .

## 6. BROADCAST

To broadcast a message a node first sends the message to the root using the collection subprotocol of Section 4. Then the message is sent to all the nodes of the network using the distribution subprotocol to be described below.

In the distribution protocol every message has several destinations, therefore, the acknowledgement mechanism of Section 3 can no longer be used. In principle the message can be sent using the BFS protocol. However, each message would require  $2D\log\Delta\log n$  time to reach all the nodes with probability  $1-\epsilon$ . A better idea is to use pipelining: Send the  $i+1$ -st message before the  $i$ -th one reaches its destination.

The protocol consists of *superphases* each consisting of  $4\log\Delta\log n$  time slots. At superphase  $t$  the root sends the  $t$ 'th message and all the nodes of level  $i$  repeatedly send the  $t-i$ 'th message (using the *Decay* protocol  $2\log n$  times).

Let  $v$  be a node of level  $i$  and  $t$  a superphase in which the nodes of level  $i-1$  send the message  $m$ . By property (2) of *Decay*, in each invocation of *Decay*, there is probability  $\geq 1/2$  that  $v$  receive a message. Since there can be no interference by messages sent from different levels (Section 2.2), if  $v$  receives any message it must be from level  $i-1$  and since all the nodes of that level send the same message, with probability  $\geq 1/2$   $v$  receives the message  $m$ . Since a superphase consists of  $2\log n$  invocations of *Decay* there is probability  $\geq 1 - 1/n^2$  that  $v$  receives  $m$  during the superphase. The probability, that  $m$  is passed successfully to all the nodes of the network is  $\geq 1 - 1/n$ .

For each message the above protocol may fail with finite probability. If the number of messages is unbounded then eventually the protocol will fail. This failure can be prevented by changing the protocol as follows:

The root appends consecutive numbers to the messages. Every node  $v$  examines these numbers and when  $v$  encounters a gap it realizes that it did not receive a message. Thereupon,  $v$  sends a message to the root requesting it to resend the missing message.

Since on the average no more than  $1/n$  of the messages will be resent, the extra load on the network is a factor of  $\sum_{i=0}^{\infty} \frac{1}{n^i} = \frac{n}{n-1}$ . Moreover, the time spent in each layer is  $O(\log\Delta \log n)$ , thus the effective rate in which message leave the root is  $O(\frac{n}{n-1} \log\Delta \log n) = O(\log\Delta \log n)$ . Also, each message requires an average of  $O(D \log\Delta \log n)$  time slots to reach all the nodes.

The previous change causes another problem, the message numbers are unbounded. An additional change can correct this problem. The messages are numbered mod  $n^2$ . After message number  $n^2$  is received each node sends an acknowledgement to the root. The expected time that all these messages reach the root is  $O((n+D)\log\Delta)$ . Thus the expected time that the all the acknowledgements reach the root is  $O((D \log n + n)\log\Delta)$ . Let  $c$  be the implied constant in the above expression. If the root does not receive acknowledgements from all the nodes by  $2c(D \log n + n)\log\Delta$  time slots after it sent the  $n^2$ th message it resends the missing messages. It can be shown that the probability that the  $n^2$ th message has to be resent is less than  $1/2$ , thus this last correction increase the load of the system by at most a factor of 2.

## 7. RANKING

Our protocols can be used for additional problems, such as ranking in expected time  $O(n \log n \log \Delta)$ :

The problem

Given  $n$  processors with distinct IDs  $id_1, \dots, id_n$ , renumber the processors,  $id'_1, \dots, id'_n$  such that  $1 \leq id'_i \leq n$  and  $id'_i < id'_j$  if and only if  $id_i < id_j$ .

The protocol

Use point-to-point communication to send all the IDs to the root. It calculates the destination of each of the new IDs and sends them to the nodes.

There is a total of  $2n-2$  messages, which require  $O(n \log \Delta)$  time (not including the setup costs of Section 2).

## 8. REMARKS AND OPEN PROBLEMS

- (1) If  $n$  is not known but only an upper bound  $N$ , we can still find a BFS tree with probability  $1-\epsilon$  in expected time  $O(D \log \frac{N}{\epsilon} \log \Delta)$ . This setup time is sufficient for  $k$ -broadcast. However, point-to-point transmissions still requires  $O(n + D \log \frac{N}{\epsilon} \log \Delta)$  time to acquire the descendant information.
- (2) If there are no IDs then the processors can randomly choose sufficiently long IDs such that with probability  $1-\epsilon$  all the IDs are distinct.
- (3) Suppose that we change the model such that in case of a conflict the receiver may get one of the messages. In this model our deterministic acknowledgement mechanism is no longer valid. A more complicated, less reliable and slower protocol exists also for this case.
- (4) In some "real life" situations processors can detect that a conflict occurred. We have not postulate this ability since we do not know how to use it.
- (5) Our protocols route messages through a spanning tree causing congestion at the root. Are there efficient communication protocols that avoid this problem?

## ACKNOWLEDGEMENTS

It is a pleasure to thank Shay Kuten for helpful discussions.

## APPENDIX

This appendix gives a formal proof why the passage of messages between levels can be modeled by a tandem queue in steady state. I.e., we prove the following,

**Theorem A:** *If the probability of a message moving from level  $i$  to level  $i-1$  is greater than  $\lambda$  then the expected time until all messages arrive at the root is bounded by the expected completion time of a tandem queue of  $D$  Bernoulli servers each having parameter  $\lambda$ .*

Consider partitions of the  $k$  messages between the levels, i.e.,  $(D+1)$ -vectors  $\mathbf{a} = (a_0, \dots, a_D)$  such that  $a_i \geq 0$  and  $\sum a_i = k$ . A *move vector* is a  $D$ -vector of nonnegative integers,  $\mathbf{m} = (m_0, \dots, m_D)$ .  $\mathbf{a}' = \text{Move}(\mathbf{a}, \mathbf{m})$  is obtained by moving  $m_i$  messages from level  $i$  to level  $i-1$ , (if  $m_i > a_i$  then only  $a_i$  messages are moved). Formally, the number of messages moved from level  $i$  is

$$\delta_i = \min(a_i, m_i).$$

Therefore,  $a'_i = a_i - \delta_i + \delta_{i+1}$ , (by convention,  $a_{D+1} = 0$ ).

A *move sequence* is an infinite series  $M = (\mathbf{m}^1, \mathbf{m}^2, \dots)$  of move vectors.  $\text{Move}^*(\mathbf{a}, M, t)$  is the

result of making  $t$  moves according to  $M$ , i.e.,

$$\text{Move}^*(a, M, 0) = a$$

$$\text{Move}^*(a, M, t+1) = \text{Move}(\text{Move}^*(a, M, t), m^{t+1}).$$

Define a partial order  $\leq$  between partitions, such that  $a \leq b$  if and only if there exist a move sequence  $M$  and an integer  $t$  such that  $a = \text{Move}^*(b, M, t)$ . (Also,  $a < b$  if  $a \leq b$  and  $a \neq b$ .)

A move vector  $\mathbf{m}$  is a *singleton* if exactly one of its components is 1 and all the other components are zero; the singleton whose  $i$ -th component is 1 is denoted  $e_i$ . The following lemma shows that we can simulate any move vector by a series of lexicographically decreasing singletons.

**Lemma A.1:** *For every move vector  $\mathbf{m}$  there is a singleton move sequence  $E_{\mathbf{m}}$  such that for every  $\mathbf{a}$ ,*  

$$\text{Move}(\mathbf{a}, \mathbf{m}) = \text{Move}^*(\mathbf{a}, E_{\mathbf{m}}, \sum_{i=1}^D m_i).$$

**Proof:** Let  $E_{\mathbf{m}} = (e_m^1, e_m^2, \dots)$  such that  $e_m^j = e_j$ , where  $j$  is the first nonzero component of  $\mathbf{m} - \sum_{i=1}^{t-1} e_m^{t-1}$ .  $\square$

**Corollary A.2:**  *$a \leq b$  if and only if there exists an integer  $t$  and a move sequence  $E$  consisting only of singletons such that  $\mathbf{a} = \text{Move}^*(\mathbf{b}, E, t)$ .*

**Lemma A.3:** *If  $a \leq b$  then for all move vectors  $\mathbf{m}$ ,  $\text{Move}(\mathbf{a}, \mathbf{m}) \leq \text{Move}(\mathbf{b}, \mathbf{m})$ .*

**Proof:** Lemma A.1 and Corollary A.2 imply that it suffices to prove the lemma for  $\mathbf{m} = e_j$  and  $\mathbf{a} = \text{Move}(\mathbf{b}, e_i)$ . If  $i \neq j+1$  then  $\text{Move}(\mathbf{a}, e_j) = \text{Move}(\text{Move}(\mathbf{b}, e_i), e_j) = \text{Move}((\mathbf{b}, e_j), e_i)$ , implying  $\text{Move}(\mathbf{a}, e_j) \leq \text{Move}(\mathbf{b}, e_j)$ .

Also if  $b_i = 0$  then  $\mathbf{a} = \mathbf{b}$ . Thus we assume that  $j = i-1$  and  $b_{j+1} > 0$ . If  $b_j = 0$  then  $\mathbf{b} = \text{Move}(\mathbf{b}, e_j)$  and  $\text{Move}(\mathbf{a}, e_j) = \text{Move}(\text{Move}(\mathbf{b}, e_{j+1}), e_j) \leq \mathbf{b} = \text{Move}(\mathbf{b}, e_j)$ . Otherwise,  

$$\begin{aligned} \text{Move}(\mathbf{a}, e_j) &= \text{Move}(\text{Move}(\mathbf{b}, e_{j+1}), e_j) \\ &= \text{Move}((\mathbf{b}, e_j), e_{j+1}). \end{aligned} \quad \square$$

The *completion time* of a partition  $\mathbf{a}$  w.r.t. a move sequence  $M$  is  $T(\mathbf{a}, M) = \min\{t : \text{Move}(\mathbf{a}, M, t) = (k, 0, \dots, 0)\}$ . (For some  $M$ 's the completion time may be infinite.)

**Theorem A.4:** *If  $\mathbf{a} \leq \mathbf{b}$  then for all  $M$ ,  $T(\mathbf{a}, M) \leq T(\mathbf{b}, M)$ .*

**Proof:** Let  $\mathbf{b}$  be the least partition for which there exists a move sequence  $M$  and a partition  $\mathbf{a}$  such that  $\mathbf{a} < \mathbf{b}$  while  $T(\mathbf{a}, M) > T(\mathbf{b}, M)$ . Let  $M = (m^1, m^2, \dots)$  and  $M' = (m^2, m^3, \dots)$ . Without loss of generality,

$\text{Move}(\mathbf{b}, m^1) < \mathbf{b}$ . By Lemma A.2  $\text{Move}(\mathbf{a}, m^1) \leq \text{Move}(\mathbf{b}, m^1)$ , thus by the minimality of  $\mathbf{b}$ ,  $T(\text{Move}(\mathbf{a}, m^1), M') \leq T(\text{Move}(\mathbf{b}, m^1), M')$ . Thus,

$$T(\mathbf{a}, M) = 1 + T(\text{Move}(\mathbf{a}, m^1), M') \leq$$

$$1 + T(\text{Move}(\mathbf{b}, m^1), M') = T(\mathbf{b}, M). \quad \square$$

Let  $p_i(\mathbf{a})$  be the probability that  $T(\mathbf{a}, M) = i$ . The *average completion time* is  $E(T(\mathbf{a})) = \sum_{i=1}^{\infty} i p_i(\mathbf{a})$ .

**Lemma A.5**  *$a \leq b$  implies that  $E(T(\mathbf{a})) \leq E(T(\mathbf{b}))$ .*

**Proof:** Let  $\mathbf{a} \leq \mathbf{b}$ . Theorem A.3 implies that for all  $M$ ,  $T(\mathbf{a}, M) \leq T(\mathbf{b}, M)$ . Therefore,

$$\{M : T(\mathbf{a}, M) \leq t\} \supseteq \{M : T(\mathbf{b}, M) \leq t\}$$

Taking probabilities

$$P(\{M : T(\mathbf{a}, M) \leq t\}) \geq P(\{M : T(\mathbf{b}, M) \leq t\}).$$

In other words,

$$\sum_{j=0}^t p_j(\mathbf{a}) \geq \sum_{j=0}^t p_j(\mathbf{b}).$$

The last condition defines that  $T(\mathbf{a})$  is *stochastically greater than*  $T(\mathbf{b})$  [Stoyan]. In this case,

$$E(T(\mathbf{a})) = \sum_{i=1}^{\infty} \sum_{j=i}^{\infty} p_j(\mathbf{a}) \leq \sum_{i=1}^{\infty} \sum_{j=i}^{\infty} p_j(\mathbf{b}) = E(T(\mathbf{b})). \quad \square$$

**Corollary A.6:** *Moving all the messages to level  $D$  does not decrease the average completion time.*

We now consider the effect of changing the probabilities of move vectors. A move vector  $\mathbf{m} = (m_0, m_2, \dots, m_D)$  *dominates* the move vector  $\tilde{\mathbf{m}} = (\tilde{m}_0, \tilde{m}_2, \dots, \tilde{m}_D)$  if for all  $i$   $m_i \geq \tilde{m}_i$ .

**Lemma A.7:** *If  $\mathbf{m}$  dominates  $\tilde{\mathbf{m}}$  and  $\mathbf{a} \leq \mathbf{b}$  then  $\text{Move}(\mathbf{a}, \mathbf{m}) \leq \text{Move}(\mathbf{b}, \tilde{\mathbf{m}})$ .*

**Proof:** Let  $E_{\mathbf{m}}$  and  $E_{\tilde{\mathbf{m}}}$  be the singleton move sequences corresponding to  $\mathbf{m}$  and  $\tilde{\mathbf{m}}$  (Lemma A.1).  $E_{\tilde{\mathbf{m}}}$  is a subsequence of  $E_{\mathbf{m}}$ . Thus, by Lemma A.1,

$$\text{Move}(\mathbf{a}, \mathbf{m}) = \text{Move}^*(\mathbf{a}, E_{\mathbf{m}}, t) \leq \text{Move}^*(\mathbf{a}, E_{\tilde{\mathbf{m}}}, \tilde{t})$$

By Lemma A.3,

$$\leq \text{Move}^*(\mathbf{b}, E_{\tilde{\mathbf{m}}}, \tilde{t}) = \text{Move}(\mathbf{b}, \tilde{\mathbf{m}}). \quad \square$$

A move sequence  $M(m^1, m^2, \dots)$  *dominates*  $\tilde{M}(\tilde{m}^1, \tilde{m}^2, \dots)$  if for all  $j$   $m^j$  dominates  $\tilde{m}^j$ .

**Lemma A.8:** *If  $M$  dominates  $\bar{M}$  and  $a \leq b$  then  $T(a, M) \leq T(b, \bar{M})$ .*

**Proof:** By induction on  $t = T(a, M)$  and using the previous Lemma.  $\square$

**Lemma A.9:** *Let  $P$  and  $\bar{P}$  be distributions of move sequences such that for all  $i$  and  $j$ ,  $\bar{P}(m_i^j > 1) = 0$  and  $P(m_i^j = 0) \leq \bar{P}(m_i^j = 0)$ . If  $T$  and  $\bar{T}$  are the respective finishing times then for all partitions  $a$*

$$E(T(a)) \leq E(\bar{T}(a)).$$

**Proof:** For each move sequence  $M$  we randomly associate a move sequence  $\bar{M}$  as follows: If  $m_i^j \geq 1$  then with probability  $\frac{\bar{P}(m_i^j = 1)}{P(m_i^j \geq 1)}$ ,  $\bar{m}_i^j = 1$ , otherwise  $\bar{m}_i^j = 0$ . From the construction:

- (1)  $M$  dominates  $\bar{M}$ , and
- (2) if  $M$  was obtained by the distribution  $P$  then the distribution of the derived move sequences  $\bar{M}$  is  $\bar{P}$ .

By Lemma A.8,  $T(a, M) \leq T(a, \bar{M})$ . The remainder of the proof is similar to that of Lemma A.5.  $\square$

The meaning of these lemmas is that the expected time until all messages reach the root is not greater than that in which

- (1) All  $k$  messages originate at a new level  $D+1$  and with probability  $\gamma$  at time  $t$  a single message moves from level  $D+1$  to level  $D$ ;
- (2) in a single time unit at most one message moves from each level, and
- (3) if level  $i$  contains messages at time  $t$  then with probability  $\gamma$  a single message moves from that level to the previous one.

To finish the proof of the theorem, it remains to justify the use of the steady-state distributions of the servers instead of the transient ones. This follows by comparing our model to one in which the servers are in the steady state. The two models differ only in their initial partition: In our case there are  $k$  message waiting at level  $D+1$  and all other levels are empty, while in the steady state-model there are additional messages in the first  $D$  levels. Thus the initial partition of the steady-state model dominates ours. The desired result follows by formally proving that if  $a$  dominates  $b$  then the expected completion time of  $a$  is greater than or equal to that of  $b$ . The formalization and proofs are similar to that of the above lemmas.  $\square$
